## Declaration of Academic Integrity

Name: Markus HADERER, BSc  
Birth Date: 13.05.1992  
Matr. Num.: 01126247

I declare in lieu of oath, that I wrote this thesis and performed the associated research myself, using only literature cited in this volume. If text passages from sources are used literally, they are marked as such. I confirm that this work is original and has not been submitted elsewhere for any examination, nor is it currently under consideration for a thesis elsewhere.

Vienna, June, 2020

## Acknowledgements

First of all, I would like to thank Dr. Oliver Spadiut and Dr. Martin Joksch for their support. They were always at my side with their advice, knowledge and expertise and helped me from the start with all the adversities that occurred. Thank you for the chance that I was allowed to write my thesis with you.

I would also like to thank Johanna Hausjell and Benedikt Hufnagl for their support with the evaluation and interesting discussions for further analysis.

I would also like to thank my colleagues in the research group for their help with occasional problems, the good cooperation and a great working environment in general. I will think back on individual conversations and experiences forever.

Last but not least, I would like to thank my family and friends!  
Thanks to my parents for the generous support of my career since childhood and the never-ending care. Thanks to my brother Michael, who always had good advice with his technical knowledge. Thanks to my girlfriend Claudia, who compassionate stood by my side and supported me in the best way imaginable.

---

## Zusammenfassung

Mikroorganismen, wie die Hefe *Saccharomyces cerevisiae*, werden in der Biotechnologie in Fermentationen eingesetzt, um unterschiedlichste Produkte - vom Bier bis hin zu Medikamenten - herzustellen. Diese industriellen Bioprozesse unterliegen strengen gesetzlichen Richtlinien, die eine Überwachung der Qualität und Quantität der erzeugten Produkte verlangen. Diese Kontrolle wird mittels Proben aus dem Prozess durchgeführt.

*Off-line* Probenahmen stellen jedoch einen Verlust an Biomasse und/oder Produkt dar und die Gefahr der Kontamination des Prozesses ist gegeben, ebenso ist die Aufbereitung der Proben sehr zeitaufwendig. *On-line* Messungen durch spektroskopische Methoden können viele Daten in Echtzeit liefern, ohne dass der Bioreaktorinhalt berührt oder gestört wird.

Mithilfe von NIR-Daten von Fermentationen aus 2016 und 2019 wurden Analysen zum Metabolismus der Hefen bei einer Biomassekonzentration von  $\leq 2.5g/L$  gemacht.

Dabei wurden die Fermentationen unterschiedlichen Prozessbedingungen ausgesetzt. Einerseits wurden Standard-Fermentationen durchgeführt, bei denen möglichst optimale Bedingungen für die Hefen eingestellt wurden. Diese dienten bei der folgenden Analyse als Sollwerte für einen ideal laufenden Prozess. Weiters wurden verschiedene Störprozesse aufgezeichnet, bei denen die Umgebung der Hefen (das Medium) kontrolliert in einen suboptimalen Bereich geregelt wurde. So wurden zu viel oder zu wenig Base zugegeben, sodass der pH-Wert den Metabolismus beeinflusst, oder die Sauerstoffversorgung unterbrochen, um einen Wechsel zum anaeroben Metabolismus zu erzwingen. Diese Störungen sollten realitätsnahe Ausfälle von einzelnen Parametern in Industrieprozessen simulieren. Die erhaltenen Ergebnisse wurden mithilfe der Software *R* aufbereitet und mittels PCA analysiert. Als Kontrolle für den vorherrschenden Metabolismus dienten *off-line* Proben.

Die Ergebnisse aus den spektralen Daten zeigten dabei, dass eine Aussage über den jeweiligen Metabolismus getroffen werden kann. Es sind sowohl die Standard-Fermentationen von den Stör-Fermentationen unterscheidbar als auch die gestörten Prozesse untereinander. Ein Vergleich mit Daten, die in 2016 aufgezeichnet wurden, lieferte ähnliche Ergebnisse in Bezug auf die physiologischen Daten. Die spektralen Daten von 2016 und 2019 lieferten unterschiedliche Ergebnisse, jedoch lagen nicht ausreichend Daten vor, um einen genauen Grund für den Ursprung dieses Unterschieds nennen zu können.

Sind die Ergebnisse der Daten von 2019 durch weitere Fermentationen reproduzierbar, so kann ein Modell für die Erkennung von Abweichungen erstellt werden. Weiters kann durch erhöhte zeitliche Probennahme festgestellt werden wie früh eine Abweichung vom Optimum erkannt werden kann. Abhängig vom Ergebnis des Trends über die Zeit, würde, bei einer signifikanten Abweichung im suboptimal-laufenden Prozess, ein früheres Eingreifen ermöglicht werden.

---

## Abstract

Microorganisms, such as the yeast *Saccharomyces cerevisiae*, are used in fermentations in biotechnology to produce a wide variety of products - from beer to medicines. These industrial bioprocesses are subject to strict legal guidelines that require monitoring of the quality and quantity of the individual products. These controls are followed up with samples from the process. However, *off-line* sampling is a loss of biomass and/or product, there is a risk of contamination of the process, and the preparation of the samples is very time-consuming. *On-line* measurements via spectroscopic methods can provide a lot of data in real time without touching or disturbing the contents of the bioreactor .

With the help of NIR data from fermentations from 2016 and 2019, analyses of the metabolism of the yeast were made at a biomass concentration of  $\leq 2.5\text{g/L}$ .

The fermentations were exposed to different process conditions. On the one hand, standard fermentations were carried out in which the best possible conditions for the yeasts were set. In the following analyses, these served as target values for an ideally running process. Furthermore, various disturbance processes were recorded in which the environment of the yeast (the medium) was deviated into a sub-optimal range. Too much or too little base was added so that the pH affected the metabolism, or the oxygen supply was interrupted to force a change to the anaerobic metabolism. These disturbances should simulate realistic failures of individual parameters in the industry. The results obtained were processed using the *R* software and analysed using PCA. *Off-line* samples served as controls for the present metabolism.

The results from the spectral data showed that a statement about the respective metabolism can be made. The standard fermentations can be distinguished from the disturbed fermentations as well as the disturbed processes among each other. A comparison with data recorded in 2016 gave similar results with regard to the physiological data. The spectral data from 2016 and 2019 gave different results, but there was insufficient data to give an exact reason for the origin of this deviation.

If the results of the 2019 data are reproducible through further fermentations, a model for the detection of deviations can be created. Furthermore, it can be determined - by increased time sampling - how early a difference from the optimum can be recognized. Depending on the result of the trend over time, an earlier intervention would be possible if there was a significant deviation in the suboptimal running process.

# Chapter 1 - Motivation

Since the FDA published an industrial guideline for process analytical monitoring of products manufactured by microorganisms in the early 2000s, the targeted quality control has constantly been improved and promoted. If a deviation in the process can be detected quickly, it is possible to work against this error at an early stage and avoid cost-intensive failures.

Especially in the biotechnological field, deviations from optimal conditions lead to irreversible changes in cells and reaction media. The better the microorganism is supplied with its optimal conditions for life and/or growth (or later in the process, the best conditions for the production and possible folding of proteins and enzymes), the better the quantity and quality of the final product. In general, the individual metabolic states of the yeast are used from food to medicinal industry, which is why a more accurate determination of the metabolic state can improve the handling of processes. *On-line* monitoring via spectrometers can give real time insights into the state of the media, but not necessarily on the cell's metabolic state.

For this thesis, fermentations operated in 2016 (fermentation number starting with 1; hereinafter "historic") and fermentations operated in 2019 (fermentation numbers starting with 2; hereinafter "new") have been compared. Using their respective spectral data of batch fermentation executed with *Saccharomyces cerevisiae*, an attempt was made to determine the metabolic states of the yeast. At minimal biomass concentration levels ( $\leq 2.5g/L$ ) and at high stirring rates, the spectral data received from the *in-situ* installed NIR probe demonstrated that (after preprocessing and analysis using the software *R*) it can be used to make comprehensible predictions on the metabolic state of the yeast. Furthermore, workflows shall be established and developed within the laboratory the study was conducted in.

## Chapter 2 - Novelty of this Thesis

Already in the 1990s, fed-batch processes using *S.cerevisiae* have been examined spectroscopically for its anaerobic ethanol fermentation with a wide concentration range of biomass (1-60 g/L) in a 5 L reactor. [1, 2] Although these processes were executed at high stirring rates (at around 300-500 rpm), the fibre optic probes were placed outside and measured through the glass-walls of the vessel. The focus of these measurements was to analyse the concentrations of water, ethanol and yeast in varying mixtures. Their results demonstrated that ethanol in complex medium can be estimated independently of the yeast concentration. Further research in water/ethanol models successfully predicted the ethanol concentration. Nevertheless, the present yeast biomass led to high scatter effects and therefore noise addition in the measurements. [1, 2] Those researches just had no or modest aeration rates in their experiments which resulted in spectra that had better quality due to no added influence by the aeration rate.

By considering high aeration rates in combination with yeast processes, attempts [3] have been made in fed-batch processes with *P.pastoris* for producing mammalian protein. Here, NIR spectroscopy was used for monitoring concentrations of biomass, glycerol, methanol and products establishing during fermentation. During the fermentation, the challenge in monitoring increased as the cell density made the non-viscous medium change to viscous and saturated the transmission monitoring.

The challenges occurring with aeration, viscosity changes of the media and agitation, are the reason why NIR is not as widely spread within industrial bioprocesses as it might seem. [4] Besides, other publications that are available in literature are most often related to at-line NIR spectroscopy or on-line measurements using simple fermentation matrices. [5] For NIR spectroscopy to be accepted as a standard monitoring device by the bioengineering and pharmaceutical industry, more on-line studies have to be made with challenging conditions and in-situ, as many processes require sterility and an immersed probe installed within the vessel for autoclaving. [5, 6]

In this study, the spectroscopic NIR probe was installed inside the reactor and exposed to vigorous agitation and aeration during batch fermentations. At the same time the biomass concentration was at  $\leq 2.5$  g/L to overcome problems with potential viscous media, to inspect if the metabolic changes are also visible at low concentrations and to reproduce the existing data as similar as possible. Successfully measuring at low concentrations would pave way for possible applications within early stages at small scale volumes to determine metabolism states prior inoculating the next scale size up. It could be shown that (after processing) the spectral data was able to differentiate between different metabolic states within the yeasts. Although no high-end equipment of spectroscopic devices was used, the data delivered a promising outcome for future applications. Being able to be independent of high-end equipment, cheaper materials can be used to monitor processes and therefore lead to a more economic use than the alternative wasteful off-line or at-line measurements.

# Chapter 3 - Introduction

## 3.1 Bioprocess Engineering

Combining the new sub-areas since the 1990s, the bioprocess engineering understands itself as the basis of industrial process development and can gain insight into the running processes with their models - both in the processes within the microorganism itself, as well as those in which the organism is located (its environment). The process of cultivating microorganisms is usually referred to as fermentation, while the vessel in which the cultivation takes place is referred to as a bioreactor. The fermentation processes can in turn be divided into an *upstream*- and *downstream*-part. The *upstream*-part of a process deals with the growth of the organism, the induction (initiation of a production) and the harvest of the microorganism. The *downstream*-process involves the processing of the target products from the cell suspension or from the cells. At a cost of 30-50% of the total manufacturing cost, it plays a significant role in testing whether a process is economical. [7]

### 3.1.1 Mode of Operation

Carrying out bioprocesses, it is possible to differentiate between three different modes depending on the feed and removal of elements of the process. These are the batch, fed-batch and continuous operation.

In a batch process, the nutrient medium is placed in a reactor and after adjusting all environmental parameters (pressure, temperature, aeration rate, pH, etc.) to an optimum, the culture is inoculated (inoculation). In the following process, apart from the environmental parameters, no change is made to the process itself (no addition of substrate during the process).

In a fed-batch process, the construction of the reactor and the inoculation are performed identically to the batch process, but substrate is added during the process (feed), in addition to any substrate present at the beginning of the fermentation. On average, the process can be carried out longer because there is no limitation of the metabolism due to missing substrate. However, the feeding has the disadvantage that the reactor filling volume increases steadily and thus a volumetric limitation of the process occurs.

In a process in continuous operation (initial setup equal to batch mode), the nutrient medium is added continuously, but also product (and/or biomass) are taken from the process. Due to the fact that feed and outflow (possibly) balance each other, the problem with the level of the fermenter can be bypassed.

The decision of which of the three modes to choose for each process is usually linked to economic factors, which have to consider not only costs but also time schedules (duration of fermentations).

### 3.1.2 Process Monitoring

Ongoing processes cannot only be monitored for their parameters by using different technologies, but also by different methods of taking samples. A distinction can be made between four possible approaches: off-line, at-line, on-line and in-line (Figure 3.1). The first two methods are mainly distinguished by the time factor. [8]

#### off-line and at-line monitoring

The *off-* and *at-line* procedures consist of a manual sampling, the analysis and evaluation of the result in a laboratory and the resulting control of the running process afterwards by entering the obtained values. The location of the analysis lab depending on the running process gives the basis for the separation into *off-* (remote treatment) and *at-line* (close to the process) procedures. Examples of *at-line* methods are the measurements by HPLC (*high pressure liquid chromatography*), while the weighting of dry biomass or the cell count are classic *off-line* methods. [9]

#### in- and on-line monitoring

The results of recorded data from *in-line* and *on-line* measurements are given at approximately the same time as their recording. While with *in-line* measurements, the values are taken directly in the process stream, the *on-line* samples are taken in a bypass of the process stream. The different application of the two methods is made depending on the process, but also according to construction requirements. Examples of both methods are the measurements using spectroscopic or fluorescence sensors, the impedance measurement or detection by NMR (*nuclear magnetic resonance*). [9]

#### Soft sensors

Due to the lack of the time component in *in-line* and *on-line* methods, an implementation of so-called *soft sensors* is an essential part of these measurement methods. *Soft sensors* receive the directly measured data on process parameters and create (calculate) - by mathematical, deterministic or statistical models - new values that are incorporated into the control of individual parameters or the entire process. In this way any processes that are "disturbed" can be detected and corrected quickly. While in fermentation processes the main focus is on the possible cost reduction together with the better ability to control product quality, in time-critical processes the time of recognition of the situation deviating from the optimum is of enormous importance (like for example in waste water treatment plants). [9]

Figure 3.1 – Sampling locations in processes [10]

### 3.1.3 Process Analytical Technology - PAT

Since manual sampling risks contaminating the sample or even the entire process, an in-/on-line measurement is to be preferred to the at-/off-line measurement. Nevertheless, for process-technical reasons, it is not always possible to monitor in-/on-line. The most widely used methods for process monitoring are still the sample-based monitoring, as it distinguishes itself by the advantage of the high degree of automation of the analytical instruments used or the direct measurement of specific analytes. Furthermore, apart from a direct application of reference methods and a parallelization, the samples taken can be kept for a longer period of time so that a subsequent analysis can also be carried out. These samples are used to ensure safe products, as well as the recording and control of *critical process parameters* (CPP) and are therefore one of the central tasks of *process analytical technology* (PAT). Accordingly, the *US Food and Drug Administration* (FDA) issued a "Guide" to biotechnological industries in 2004. [11] Sample-based measurements are often used in combination with *Standard PAT Tools* (e.g., in-line sensors for temperature, pH-probes,  $pO_2$ -values). Even gas flow analysers or infrared measurements can be combined to a higher level of process analytical methods. These advanced PAT tools enable continuous process monitoring by linking the continuous signals of the sensors with mathematical models to soft sensors. The main reason that these sensors have not yet replaced sample-based process monitoring is their low specificity. [11, 12, 13] However, for modelling and implementation of a soft sensor, the data from single, one-dimensional (*univariate*) measurements, such as pH- or temperature-values alone, are not sufficient, as they only represent part of the overall process. It is necessary to link a large number of univariate quantities or to use the superimposed information from the multidimensional (*multivariate*) data acquired by a corresponding detector (for example: NIR spectra; see 3.3.2). [9]

## 3.2 Microorganism

The yeast used in this thesis<sup>1</sup> is commonly referred to as "baker's yeast" and is the genus of *Saccharomyces* (= ancient Greek: "sugar mushroom") which has been used for millennia for the production of food such as bread, wine or beer. The *Saccharomyces cerevisiae* is a eukaryotic microorganism whose genome consists of over 12 billion base pairs and comprises approximately 6275 genes. A single cell has a diameter of 5 to 10  $\mu\text{m}$ . The reproduction happens vegetative via budding or pullulation, but it can also occur in hyphae form [14] or produce ascospores [15]. The yeast cells have glycoproteins (adhesins) on their cell walls, which lead to the formation of flakes. This flocculation is caused by stress during transcription, e.g. under nutrient limitation, and plays an important role in the separation of the cells from the fermentation medium. Since the harvest step of a process is done via centrifugation and filtration and it is very cost-intensive. The flocculation is used to improve and support the harvest. Via agglomeration of thousands of yeast cells, which leads to an increased particle diameter (increase from 10 to 500 $\mu\text{m}$ ), the sedimentation rate can be increased by a factor of 2500. [7]

### 3.2.1 Metabolism

Baker's yeast can metabolize the energy that is needed to its household in both anaerobic and aerobic ways. If the organism is able to produce energy in both anaerobic (via fermentation; reductive) and aerobic (via respiration; oxidative) conditions, the organism is designated as *facultative anaerobic*. [7] For a more detailed explanation of the metabolic energy production of yeast, the following assumptions (1-7) are made (based on the definition of the model description from *Sonnleitner and Käppeli* [16]):

1. Yeast growth in batch mode with glucose and ethanol as nutrients follows nearly ideal Monod kinetics.
2. There are no by-products in significant quantities during the process; the resulting main products in diluted cultures are biomass,  $\text{CO}_2$ ,  $\text{H}_2\text{O}$ , and, under appropriate conditions, ethanol. The recovery of carbon is always nearly 100%.
3. The specific oxygen uptake rate in oxidative metabolism is linearly correlated with the specific glucose uptake rate such as subcritical glucose flux or ethanol growth. Under oxidoreductive conditions of supracritical glucose flux (conditions in which ethanol is produced by the cell), the specific oxygen uptake rate remains constant at its maximum regardless of the growth rate.
4. Glucose inhibits the uptake of ethanol as a substrate insofar as it is present in a measurable amount.

---

<sup>1</sup>see 9.1.1 for more details on the yeast

5. Glucose can be metabolized both aerobically and anaerobically, but at a different rate and efficiency.
6. Ethanol can only be metabolized anaerobically.
7. The composition of the biomass does not change, regardless of whether ethanol is produced or not. The composition of the biomass changes slightly as it grows on ethanol as the primary substrate compared to glucose, but the differences are within an analytical error.

Based on these assumptions, metabolic energy production based on glucose and ethanol as substrates can be subdivided into two (respectively three) types: the oxidative degradation of glucose (Formula 3.1) and ethanol (Formula 3.2) and the reductive degradation of glucose (Formula 3.3).

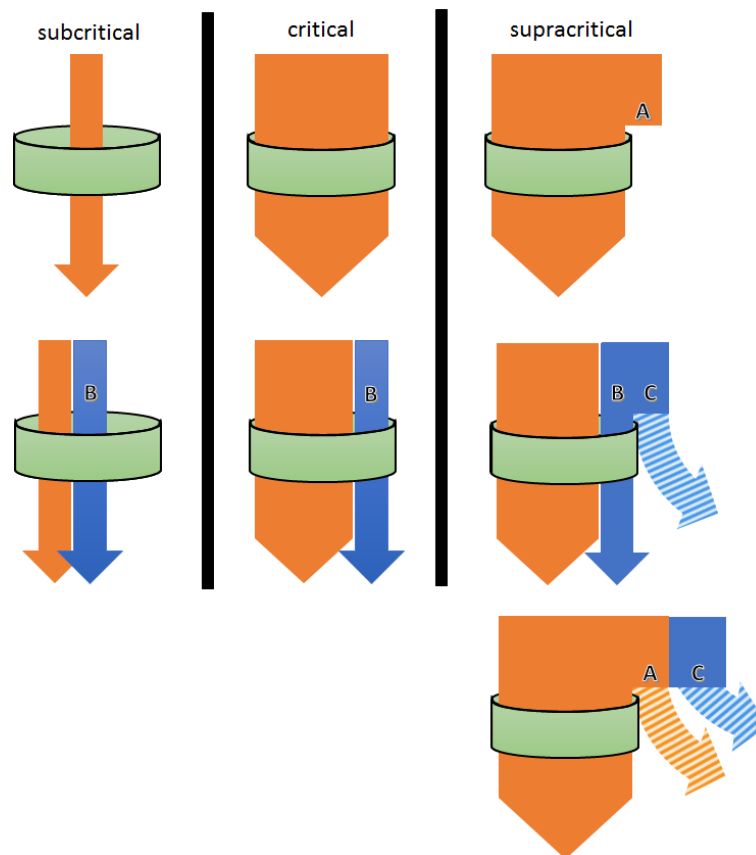

The molecular weight of the resulting biomass with the chemical formula  $\text{C}_1\text{H}_{HX}\text{O}_{OX}\text{N}_{NX}$  is calculated from elementary analysis of the biomass itself. The nitrogen source can be neglected in terms of nitrogen atom balance because the nitrogen atom(s) will not change the oxidative state. However, consideration must be given to the number of hydrogen atoms present in the nitrogen source. [16]

It is believed that the cell's respiratory capacity controls the glucose and ethanol metabolism in growing cells as well as product formation. It represents a bottleneck for oxidative substrate utilization. Figure 3.2 shows the flow of substrates and the respiratory capacity, shown as a bright green ring (bottleneck), for the respective substrate combinations of glucose and ethanol. A column-wise distinction can be made between the three types of substrate usage - *subcritical*, *critical* and *supracritical*.

In the case of subcritical metabolism, there are insufficient amounts of substrate to fully utilize the respiratory capacity (left column). If more substrate is added to the medium, it can be oxidatively consumed up to the critical stage (the bottleneck is completely filled; middle column). If the amount of substrate exceeds the maximum possible oxidative conversion (more substrate available than fits through the bottleneck), the supracritical state occurs (right column).

The top row of Figure 3.2 describes the case in which only glucose (orange arrows) is present as a substrate. The glucose is oxidatively consumed until the supracritical state is reached. In this state, the maximum possible amount is oxidatively metabolized, while other existing glucose is reductively converted to ethanol (fermentation) (striped orange arrow; A). If both substrates, glucose and ethanol (blue arrows), are present in the medium (second and third row) with glucose in an insufficient quantity to reach a supracritical state, all the glucose is oxidatively metabolized and the remaining respiratory capacity is used to oxidatively metabolize the available ethanol (blue arrow; B).

If the amount of substrates exceeds the respiratory capacity, the existing ethanol that is present in the medium during a supracritical state cannot be consumed reductively (third row; C). It can only be metabolized when the respiration capacity for oxidative degradation is available again (second row, far right; B).

**Figure 3.2** – Respiratory capacity in *bottleneck*-representation (green ring); adapted from [16]  
The arrows indicate substrates glucose (orange) and ethanol (blue) in three metabolic states

### 3.2.2 *Saccharomyces cerevisiae* in bioprocessing

One of the oldest food-manufacturing processes is bread making and especially *S.cerevisiae* strains are chosen for its dough-leavening characteristics. Since the 1990's, the recombinant-DNA technology has led to new formulation, ingredients and process conditions and now the role of baker's yeast changed into the possibility of using it as a cell factory for expression of heterologous genes. [17, 18] *S.cerevisiae* is nowadays used for production of several large volume products such as insulin and insulin analogues, but also human serum albumin or hepatitis vaccines. In 2012, 20% from those so-called "biopharmaceuticals" were produced by *S.cerevisiae*<sup>2</sup>. The yeast's eukaryotic model system enables production and proper folding of many human proteins. In addition, the products can be secreted into the extracellular medium, making it possible to optimize subsequent purification and in many cases, yeast can perform *post-translational modifications* (PTM) of the produced protein, including acylation, glycosylation and numerous other. [19, 20]

The secretory pathway in yeast is quite complex and has traditionally focused on transcriptional regulation of the protein production. The goal to further improve this protein production can be studied by engineering the pathway [20], and via metabolic engineering cycles where systems biology tools are implemented for the design of improved cell factories. These approaches need detailed analysis of the cellular metabolism and physiology. A major limitation in using those approaches of model engineering is the difficulty to obtain information about the metabolic state of the microorganism (yeast) within the process. [19] This information can be obtained by using process parameters to develop models allowing a rough insight into the process (see 3.1.3).

---

<sup>2</sup>40% of production uses mammalian cell lines, mainly using chinese hamster ovarian cells (CHO), and for another 30%, *E.coli* cells are used. [19]

### 3.3 Infrared Spectroscopy

#### 3.3.1 Near-Infrared Spectroscopy

For a long time, near-infrared spectroscopy (NIR) has been treated as an addition to analysis done via ultraviolet/visible- (UV/Vis) and mid-infrared (MIR) laboratory spectrometers (Figure 3.3). This changed at around 1980 and nowadays NIR spectroscopy is used in a variety of sectors for its availability of efficient chemometric evaluation routines.

Especially the increasing costs and legal requirements for quality control, conclude to the fact, that the NIR spectroscopy is the method of choice for industrial on-line control [21].

Currently used off-line methods, such as HPLC, NMR, mass spectroscopy and wet chemicals methods, combined with diverse in- and on-line control and measurement techniques, are time consuming, need solvents for their application and/or cannot be applied remotely.

NIR has the potential to be, or already is, the new instrumental accessory for industrial process monitoring in a wide field of applications (see 3.3.2) [4, 21]. For bioprocesses with a high cell density or processes, where the biomass has a complex structure such as filamentous fungal or Saccharomycete culture and can disturb the transmission, reflectance spectroscopy mode is used. Besides off-line and at-line approaches the spectroscopy probe can be placed on-line and *ex-situ* where the device is physically outside of the reactor being placed on the glass wall or using a flow-through cell or *in-situ* where the device is placed into the reactor like a pH-probe. The direct approach of the *in-situ* method was chosen for this thesis, since, on the one hand, the set-up of the used bioreactor did not allow *ex-situ* application and on the other hand the direct measurement method allows for monitoring both the chemical and biological changes in the complex broth composition. [21]

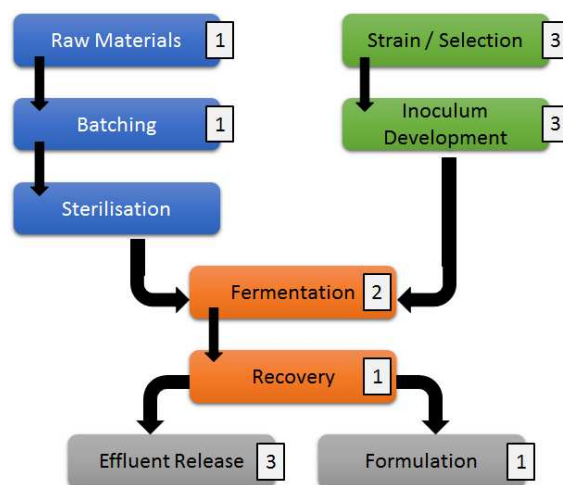

Figure 3.3 – Electromagnetic spectrum with its respective influence on electrons [10]

### 3.3.2 Application of NIR

Mainly used for quality control of raw materials, intermediates or finished products, NIR spectroscopy can be found in different technology fields like agricultural, food, chemical and pharmaceutical industry. Being a cost efficient and fast alternative to other control methods, the NIR spectroscopy is used for trend analysis of manufacturing processes to support the development of an automated control system. In the food industry, the measuring of protein or fat concentration in beverages like milk or cereals is performed, or the level of moisture in wheat, barley and other grain materials inflicting their quality are tested. Also, the determination of alcohol content in beer, wine and other alcoholic beverages, and additionally to alcohol content, tests for specific amino acids, acidity and total sugar were performed.

The pharmaceutical industry is increasingly using NIR for their in-process routines to analyse the drying and granulating process. Further, tablets are tested for their hardness and conformity as well as powder blending on their grain sizes. Beside the mostly mentioned qualitative measurement performed with NIR spectroscopy, also quantitative analysis can be executed. Especially the agricultural industry examines the composition of the foul and recovered organic solvents. The analysis of the composition of soil, the uptake of nitrogen and the quality control of insecticides are primarily using NIR methods. [4, 21]

While all these applications of NIR spectroscopy in diverse industrial fields have been established over many decades, the use of NIR spectroscopy in bioprocesses offers the potential of (near) real time monitoring. The different stages of where NIR spectroscopy can be (or is already) used in bioprocesses can be seen in Figure 3.4. The proven use in fermentations at lab scale (Figure 3.4, 2) arises from the fact that fermentations must be divided into two major subgroups regarding monitoring by NIR spectroscopy.

**Figure 3.4** – Areas of NIR spectroscopy application in bioprocesses; adapted from [4] (1- commonly used; 2- utility proven at lab scale; 3- utility under investigation)

Working with mammalian cells, sparsely aerated and lightly agitation is used which are considered spectroscopically simple and "clean" (following Newtonian rheological behaviour), these processes have been studied both at-line [22, 23, 24] and *in-situ* [25, 26] already.

The conditions of agitation and aeration in cell cultures using fungal fermentation or bacteria is much more vigorous [27, 28], presenting significant challenges to the use of NIR. The high cell density cultures of bacteria (such as *E.coli*) or yeasts (like *Pichia Pastoris* or *Saccharomyces cerevisiae*) present great levels of complexity. Although these different fermentations differ in their physical and chemical nature of their matrix (bioprocess fluid), NIR spectroscopy can be used to successfully monitor them (partially). [4]

### 3.3.3 NIR in Bioprocesses - State of the Art

Industrial processes and its variables can be monitored via different sensors and measurement methods. Those include measurements of process variables in gas and liquid phase as well as biomass and other solids. Spectroscopic sensors are just a small part of the available sensors for determining components within the liquid phase. Since 1999, a great number of studies have explored the use of NIR spectroscopy for monitoring bioprocesses as it can be useful in providing several applications, for example within automatic control systems, process optimization and on-line quality assessments. [5]

As they enable multiparametric, non-invasive measurements of process variables and trajectories, the robust free beam NIR process analysers are indispensable tools within the PAT and *quality by design* (QbD) framework. Already in 2013, the data acquired by NIR sensors could be used together with quantitative and multivariate analysis to provide information on-line. Being easy to interpret, they led to better process understanding. This made it possible for an operator to intervene earlier and improved overall performance. [29]

In [30], the advantage of real time measurements and weaker absorption in contrast to MIR are mentioned. Regarding the first advantage, "real time" can be interpreted variously in terms of process sampling used in comparison to the process variable to be measured, as some sampling methods need around 30 minutes of evaluation, but depending on the measured variable, for instance an metabolic change that can have an hour-long adjustment period, the measurement is fast enough for the purpose of process control. Nevertheless - speaking of NIR sensors - measurements are available immediately, independent of the monitored process variable. Regarding the second mentioned advantage in [30], weaker absorption bands result in lower sensitivity but higher penetration depth (than MIR) and are suitable for highly absorbing samples [31]. As NIR is used invasively and non-invasively in pharmaceutical industry - for different measurements such as dissolution rates, blending homogeneity, water content during drying -, it is becoming an effective tool for the PAT initiative in pharmaceutical processing. Due to the fact that bioprocesses most often consist of aqueous solutions that change their dilution and contain varying cell concentrations, bioprocesses are much harder to monitor via NIR than chemical drug manufacturing. [30]

However, NIR spectroscopy is able to cover a wide spectrum of upstream applications in biotechnology. Several studies monitored biomass concentrations of different microorganisms - amongst others also *S.cerevisiae* in 2007 [32]<sup>3</sup>, resulting in limited information on biomass if the media is very turbid. Despite its many possibilities of application, NIR spectroscopy is not routinely used in upstream and downstream processes. Only few studies show results of using spectroscopic NIR approaches with bacilli, yeasts (*P.pastoris*) or mammalian cell fermentations. [3, 33] Just few applications of NIR spectroscopy in downstream units of mammalian process can be found.<sup>4</sup>

As far as the NIR spectroscopy can be used to monitor both - chemical and biological - process variables in upstream units as described above and in scale-up as described in [35], one has to bear in mind that the specific NIR absorption bands of process media and biomass alone do not provide enough information. Often multivariate analysis and preprocessing is needed to extract the detailed information of interest. [36] The technology is further limited by its dependence on calibrations (derived from single reactor at given time) [6], and the immersed probes are subject to a chemical broth and can therefore be blocked during measurements by solids or air bubbles. [3]

In general, raw NIR spectra have the disadvantage that even the slightest particle influences the outcome, maybe even at more than one wavelength, which results in noise peaks. The more diffuse the measured sample, the more noise is added to the spectra and agitation and aeration in bioprocesses exacerbate these circumstances.

To prevent these noises from overlaying essential information, the aforementioned preprocessing is required.

NIR shows a great potential for being used as the main sensor technique within industrial processes. It appears that NIR is more often used in research at lab-scale than in industry. Reasons for that could be the huge amounts of documentations that are needed for implementation and the possibility that industrial applications often underlie secrecy. [37]

---

<sup>3</sup>For comparison of two different sensor methods (infrared and dielectric spectroscopy) within fed-batch processes at high concentration levels.

<sup>4</sup>Applications of freeze-drying and crystallization are described in [34].

### 3.3.4 Spectral Preprocessing

Signal processing is performed to transform spectral data prior to calibration and further multivariate data analysis. In modern NIR spectroscopy of complex composite samples it is quite common that effects appear which cannot be easily quantified with reference analysis. Those noises arise from the interaction of compounds, light scattering, effect on the baseline and many others. Such interference can manipulate the outcome of following calculations and model predictions. [21] Therefore, the noises have to be removed as good as possible. This signal processing is also referred to as data pretreatment and aims at increasing the signal-to-noise ratio via different methods resulting in more distinctive peaks.

Although data preprocessing is almost always necessary, it should be kept in mind that every peak in a spectrum contains information. Applying too many methods or trying too hard to remove noise from the spectrum may result in the loss of essential information about the state of the system at the time of recording.

#### Smoothing

The basic approach of smoothing is the reduction of noise by averaging multiple measurements. The drawback is a sub-optimal cutting of frequencies in which frequencies that include essential information may be cut off together with those being just noise. Two more advanced approaches are the *moving average method* and the *Savitzky-Golay-Filter*.

The Savitzky-Golay method fits a low-degree polynomial through the data points and can be varied for its window size (number of data points) and order of derivative, resulting in a local convolution filter. [21]

#### Baseline Corrections

The baseline correction occurs when systematic deviations distort the baseline. Corrections are made by using vertices, by functions as described above at the smoothing approach or by applying derivatives. A positive side effect is the enhancement of the spectral resolution by the application of the derivatives, but the original appearance of the spectrum is lost which can complicate subsequent calculations by PCA (*principal component analysis*) or PLS (*partial least squares*). [38]

#### Multiplicative Corrections

Although many methods on multiplicative corrections exist, such as "Norris Regression" and MSC, the *standard normal variate* (SNV) was chosen as it gives nearly equivalent results as MSC without the required additional information on the product samples. SNV calculates the mean and standard deviation of an entire spectrum. Using these quantities, the individual spectra can be centred around zero. If a correlation between the pathlength changes of the wavelength and the standard deviation exists, the method delivers multiplicative standardisation. [21, 38]

## 3.4 Multivariate Data Analysis

The recorded data sets are multidimensional information that cannot always be displayed, which is why multivariate data analysis is used to help re-render the data or reduce dimensions. Using a variety of methods, such as PCA, the overview of multidimensional problems can be recaptured, and any relationships of data become visible.

### 3.4.1 PCA

Principal component analysis has the mathematical advantage over methods such as *multiple linear regression* (MLR) that any uncorrelated data does not prevent the computation of linear models. Using PCA, multidimensional datasets can be placed on a - ideally two-dimensional - "lower" dimensional base. The factors that have the greatest impact (biggest variance) on the data are used to create new coordinate systems based on these so-called *principal components* (PCs). How this realignment of the data takes place so that maximum information can be obtained in the new representation depends on the direction of the maximum scatter of the data plotted on the new orthogonal axes. In the two-dimensional case, a system (diagram) of two axes is created, but it does not always make sense to display the data in two dimensions, since otherwise too much potentially important information could be lost. Regardless of how "n-dimensional" the new axis system should be, the following procedure is generally used: The dataset searches for a direction that describes the maximum scatter of the dataset. The first axis is placed in these. In the next step, a new axis which is orthogonal to the first axis, describing the maximum scatter in its direction, is put into the system. For the two-dimensional case, the resulting system would be the final result. For multidimensional systems, finding the new axes, assuming that they are always orthogonal to the previous axis and describe the maximum scatter in their direction, is repeated until the result satisfies the requirements or the maximum number of dimensions (depending on the data set) is reached. Due to the orthogonality of the axes to each other, the correlation between any two components is always zero. [38, 39]

# Chapter 4 - Goals and Scientific Questions

The aim of this diploma thesis was to provide a basis for the modelling of yeast batch fermentations (*S.cerevisiae*), with the requirement that this modelling is based on spectral process data and can be combined with process monitoring systems.

The fermentations performed during this study shall be used to establish and develop workflows at the laboratory. For this purpose, batch fermentations were carried out at lab-scale whose structure should be as identical as possible to the fermentations already carried out by the research group in 2016.

During the processes performed in 2016, the spectral data was recorded but was not used for further analysis or modelling. By comparing the new and the historic fermentations, it should be shown that already existing data can be used for modelling too, insofar as they are physiological similar to the new ones and reproducible.

## 1<sup>st</sup> Scientific Question

*Can spectral data capture deviations in metabolic states in yeast at low biomass concentrations?*

The historical fermentations were carried out at biomass concentration levels of  $\leq 2.5 \text{ g/L}$  which could make it difficult to obtain adequate spectral data of the organism's metabolic states. Process-specific circumstances can lead to different behaviours of the yeasts in the solution which can have a tremendous impact on a final product in an industrial process.

## 2<sup>nd</sup> Scientific Question

*Are the deviations distinguishable from each other within PCA analysis?*

Being able to monitor a change in the metabolic state, the operator would be able to intervene at an early stage of the process which is not performing at an ideal level. If one is further able to differentiate between a disturbance of the pH and the oxygen supply, or even between different pH values (too basic or too acidic), the regulation back to the optimum would be easier.

## Chapter 5 - Material and Methods

The historic as well as the new fermentations were part of a DoE (*design of experiment*) including fermentations that were disturbed during process, by shift of pH and aeration, and ones that were performed in as optimal conditions as possible (so called "Golden Batches (GB)"; hereinafter "standard fermentation"). Those disturbances were chosen because of their possibility to occur in industrial processes if one or more control mechanisms stopped working.

The disturbances on the pH included two modes: *base off* and *base on*. Both modes shall resemble the failure of tubing between reactor and base, emptying of stock solution and/or failure of pH-probe, resulting in insufficient to no base addition (*base off* mode) or extensive addition of base to suboptimal conditions (*base on* mode). In the *base off* mode fermentation, the base supply was terminated after 120 minutes of process. In the *base on* mode fermentation, the pH control system was shut down after 120 minutes, resulting in continuous addition of base towards pH-values beyond 10.

The disturbance on the aeration rate shall resemble a failure in oxygen supply resulting in a change from respiration to fermentation in the metabolic system of the yeast. In the *air off* mode, the air supply was shut down after 120 minutes. Respectively to their individual disturbance, those fermentations are referred to as "base off-", "base on-" and "air off-" fermentations.

The DoE of the historic fermentations included 10 standard and 5 disturbed fermentations. While the standard fermentations were performed similarly to the new standard fermentations, the disturbances were chosen differently. The historic disturbances included a *base off* fermentation<sup>1</sup>, an *air off* fermentation, a fermentation with low stirring speed, an addition of  $CuSO_4$ <sup>2</sup> during fermentation and a fermentation with more biomass in the initial setup of the fermentation.

---

<sup>1</sup>There was no *base on* fermentation performed. Therefore, only *base off* fermentation results will be compared with the historic data set.

<sup>2</sup>Copper-Sulfate shall simulate a yeast-toxic substance in the medium. Because yeasts are used for the production of enzymes and other products, in a process with genetically modified yeasts, they may produce and release a substance into the fermenter medium that can have a poor or toxic effect on the yeast.

## 5.1 Culture Medium and Chemicals

For all fermentations, a uniform medium with nutrients was weighed in to create an optimal environment for the microorganism at the beginning of the process. In Table 5.1, in the leftmost column, one can find the predetermined target amount of media components to be weighed, which were each dissolved in 4.5 L tap water. The columns to the right of it contain the weights for the corresponding fermentations, indicated by their process numbers.

**Table 5.1** – Weighted amount of the ingredients of medium, substrate (glucose) and biomass for the six standard fermentations (F295 - F299)

Chemicals	Target-Amount [g]	Actual-Amount [g]				
		F-295	F-296	F-297	F-298	F-299
$(NH_4)_2SO_4$	72.00	71.935	71.988	72.001	72.026	72.018
$MgSO_4 \cdot 7H_2O$	5.20	5.203	5.198	5.197	5.209	5.198
$(NH_4)H_2PO_4$	5.60	5.616	5.601	5.594	5.604	5.590
$KCl$	22.50	22.502	22.496	22.501	22.498	22.502
$CaCl_2 \cdot 2H_2O$	1.89	1.882	1.886	1.893	1.894	1.885
Glucose	9.50	9.508	9.526	9.502	9.494	9.495
Yeast	10.00	10.000	10.000	10.014	9.814	10.028

After the preparation of the medium, the reactor was assembled (the installed instruments are listed in chapter 9.1.2). The stirring was set to 800 rpm and 11 ml of trace element solution were added. For this, a single volume of 200 mL was prepared (stock solution) and 11 mL were taken for each fermentation. The composition for the trace element stock solution<sup>3</sup> is shown in Table 5.2.

After the trace element solution, 2 drops of the antifoam agent *Struktol J673* were added. This agent should prevent too much foaming, since the foam could cause an inhomogeneous broth.

After the medium in the reactor was completely assembled, the recording was started in the operating system. After around two minutes, the initial biomass was added to the fermenter. The exact amount of yeast for each fermentation can also be found in Table 5.1. The fermentations were monitored by the operator via process control system and terminated after indication of gassing factors ( $CO_2$  and  $O_2$ ).

<sup>3</sup>The data in Table 5.2 refers to a final volume of 50 mL.

**Table 5.2** – Ingredients of the trace elements stock solution

Chemicals	Target-Amount [g]	Concentration [mg/L]
$CuSO_4 \cdot 5H_2O$	48	2.4
$MnSO_4 \cdot H_2O$	210	11.6
$ZnSO_4 \cdot 7H_2O$	180	9.9
Ca-D(+)-pantothemat	200	11.0
Myo-inositol	2100	115.5
Biotin	20	1.1
$FeCl_3 \cdot 6H_2O$	300	16.5

## 5.2 Processing of the Data

During the fermentations, the data from all instruments and the set process parameters were set up via *SIEMENS PCS7* and the data was collected electronically via the process analytical software *SIEMENS SIPAT*. In addition to electronic monitoring, samples were drawn off-line at different time points within the processes.

All process parameters of the historic and new fermentation were set as identical as possible, the same applies to the used instruments<sup>4</sup>, chemicals<sup>5</sup> and processing operations of the off-line samples<sup>6</sup>. For the processing of the on-line data, a more identical preparation could be performed. The following sections shall explain the process of data collection and analysis of off-line (5.2.1) and on-line data (5.2.3).

<sup>4</sup>In 2016 other gassing probes were used to measure and collect the aeration data of  $CO_2$  and  $O_2$ .

Fortunately, there exists data in which the processes were monitored by the "old" and the "new" aeration probes simultaneously. Those data sets were used to convert the historic aeration data into values similar to the "new" instruments, making it possible to compare the data sets.

<sup>5</sup>As described in the section regarding the yeast strain (see 9.1.1), no statement can be made on strain consistency.

<sup>6</sup>In 2016 no measurements regarding the supernatant were performed in any kind.

### 5.2.1 Off-line Data Analysis - Collection and Pretreatment

At different points in time during the bioprocesses, small volumes (at around 20 mL per sample) of broth were collected via flexible tubing. Six test tubes were filled with 3 mL of broth solution respectively. Those tubes were centrifuged, and the supernatant was collected prior to further preparation of the cell pellets. This supernatant was frozen and stored at a temperature of  $-4^{\circ}\text{C}$  until transportation for HPLC measurements. The cell pellets were washed with water and centrifuged again. The newly supernatant was withdrawn and the cell pellets were put in the heating chamber at a temperature of  $65^{\circ}\text{C}$  for at least three days<sup>7</sup>. The dried samples were weighted and their dry cell weight (DCW) was used for further evaluation of the physiological data.

#### HPLC Measurement

The supernatant samples were transported frozen and thawed just before the HPLC measurement. Prior to the measurements, standard solutions of ethanol and pyruvic acid were made. These standard solutions and water (blank test) were analysed simultaneously to the measurement of the samples. The sugar concentrations were analysed via HPLC (Thermo Scientific) on a Supelcogel column (Supelco Inc.) at a constant flow of 0.5 ml/min at  $30^{\circ}\text{C}$ . The mobile phase consisted of 0.1%  $\text{H}_3\text{PO}_4$  (85%) and ethanol and pyruvic acid were detected with a Shodex RI-101 refractive index detector (DataApex).<sup>8</sup> [40]

The supernatant was especially analysed for the amount of ethanol in the broth at the specific time stamp, but also pyruvic acid (and possible other by-products) of the yeast's individual metabolism.

---

<sup>7</sup>Due to limitations in laboratory accessibility on weekends, the dried samples could not always be further processed and analysed after exactly 72 hours. All samples were dried at least 72 hours.

<sup>8</sup>Analysis of the chromatograms was performed by Johanna Hausjell, MSc using *Chromeleon Software* (Dionex).

## 5.2.2 Offline Data Analysis - Physiological Data

The results from the DCW and the HPLC measurements were inserted into an \*.xlsx-file. Six parameters were analysed to get an insight into the metabolic state of the yeast as good as possible and to be able to compare the historic and new fermentations on a physiological level.

### Respiratory Quotient

Dividing the metabolism of *S.cerevisiae* into anaerobic fermentation and aerobic respiration, the respiratory quotient, describing the ratio between  $CO_2$  and  $O_2$  in the gassing rates, is an important tool to determine the metabolic state. Monitoring the  $CO_2$ - and  $O_2$ -values in the off-gas, this factor was also used to determine the end of fermentation during process.

### C-Balance

As glucose is the only carbon source (in the beginning) the distribution of the C-atoms can be used to determine the metabolic state. The C-Balance estimation is used to check robustness of experimental information.

### Volumetric Growth Rate of Biomass $r_X$

As substrate is metabolised, biomass grows in addition to self-sustainment. This growth rate is defined by the increase of biomass over time and expressed by  $r_X$ .

### Volumetric Substrate Uptake Rate $r_S$

The substrate is metabolised for self-sustainment and growth. It is defined by the uptake of substrate over time and expressed by  $r_S$ .

### $\frac{X}{S}$ Yield

The amount of substrate used for the formation of new biomass can be calculated using the  $\frac{X}{S}$  yield ( $Y_{\frac{X}{S}}$ ). If the necessary substrate consumption for cellular maintenance is neglected (3.2.1), the  $\frac{X}{S}$  yield corresponds to the ratio between the formed biomass and the substrate uptake.

### $\frac{CO_2}{S}$ Yield

The  $\frac{CO_2}{S}$  yield ( $Y_{\frac{CO_2}{S}}$ ) describes the ratio of produced  $CO_2$  regarding to the substrate uptake.

### 5.2.3 On-line Data Analysis - Collection and Transfer

The collected data was transferred in \*.csv-data format from the process control unit to data storage. Due to the fact that the process control software stores all data equally, the order of rows and columns were not changed in order to perform each processing step identically for each data file. The data was loaded into  $R$ . There was no treatment done within the files prior to processing with  $R$ .

### 5.2.4 Online Data Analysis - Preprocessing of the Data

The code used for processing the spectral data (see 9.2) consists of three major parts. In the first one, the data is inserted into the program and unified. The further process steps after this part can be further divided into individual and collective treatment. The second part deals with the smoothing and correction of the baseline. The third part deals with the statistical analysis of the data.

#### Unifying of the Data

Prior to processing the data with statistical methods, the spectral data was cut from the whole data set. The spectral data was plotted in 3D plots for first optical examination. It was found that the data points next to the limits of the wavelength range (1350nm and 1650nm) were extremely noisy. Failure of the connection of the NIR probe and its software to the process monitoring software led to the fact that in the beginning of each fermentation some time stamps had collected no spectral data but only process data. The noises and partially missing data points in the beginning led to the cutting of the data set. Respectively 10nm of wavelength range from the limits and the first 45 minutes of each fermentation were omitted. The data was then examined for missing NIR data during the process and the corresponding entries were removed from the record. Thus, it was given that all data sets did not contain missing spectral values. After this step, the spectral data were identical in size (number of variables), except for the time length. The individual wavelengths (281) are found as variables in the columns, the absorptions recorded every minute as objects in the rows of the data matrix.

## Smoothing and Baseline Correction

Taking the data from the previous preprocesses, a standard normal variate method (SNV) was carried out at first. This was done to correct the baseline row-wise. The data sets were reduced from noisy peaks by smoothing. For this, a Savitzky-Golay (SG) polynomial fit was applied. The window size was 13, the polynomial order was 1 and the first derivative was calculated. The Savitzky-Golay fit was applied on the data that has already been smoothed via SNV. Prior to further analysis the results of unifying, SNV- and SG-processing were analysed optically via 3D-plots. These initial checks by visual inspection were used to investigate the effects on the functions for correctness. Likewise, the best settings for the SG-filter (polynomial order, window size and derivation) could be found. This entire process was carried out twice: once just with the data from the first processing step and once with the data from the first processing step with additional application of the "MeanInt" function. The self-written function "MeanInt" should serve to form the arithmetic mean over the data, in the interval  $+i$  and  $-i$  around the sample  $x$ . The sample  $x$  was taken every 20 minutes and the interval  $i$  was set to 7. The two resulting data sets were further analyzed by PCA.

### 5.2.5 On-line Data Analysis - Principal Component Analysis

There were two analyses performed via principal component analysis (PCA). In the first place, on each fermentation data a PCA was performed individually. This was done to determine the biggest variance for each fermentation and to look for possible outliers. For the second PCA analysis an additional column was inserted including the number of fermentations in each row for the respective fermentation data. The resulting data sets were bound together row-wise, resulting in one big data set. This part of analysis was done so that the axis of rotation is the same for the largest variance in each process. The results and conclusions on those analyses can be found in the respective chapters (Chapter 6.4.3 and Chapter 7).

# Chapter 6 - Results and Discussion

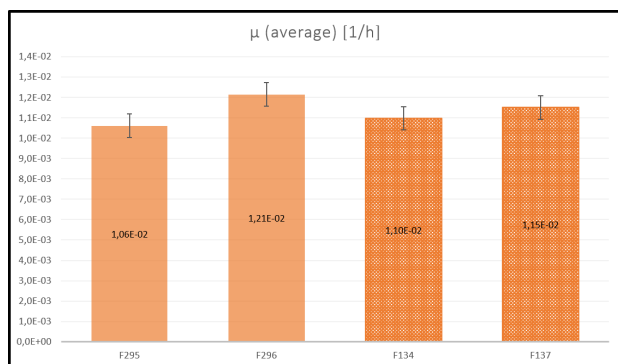

In the following sections (6.1-6.3), the physiological data, required from off-line samples, and the spectral on-line data of the process were compared and analysed in accordance with their specific fermentations (standard vs. disturbance). The fermentation data sets were analysed using the six parameters mentioned in chapter 5.2.2. The fermentations were correlated with each other, divided according to their fermentation types (e.g. historical standard with new standard or specific historical disturbance with corresponding new disturbance). Furthermore, the metabolic states of the new fermentations were compared regarding the six parameters and if their spectral fingerprint can give an insight into the metabolic state. In the diagrams, the error bars represent the standard deviation and the historic data is represented by dotted bars. The colour code shall help to distinguish between processes. The supernatant analyses via HPLC were not included in the data analysis since for the metabolite ethanol as well as for pyruvic acid, no concentrations above the analysis limit could be determined. Since it was assumed that ethanol and pyruvic acid were the most frequently present metabolites in terms of quantity, and even no ethanol was found above analysis limit in the supernatant of the anaerobic fermentation, possible further metabolites in the broth were neglected.

## 6.1 Standard Fermentations

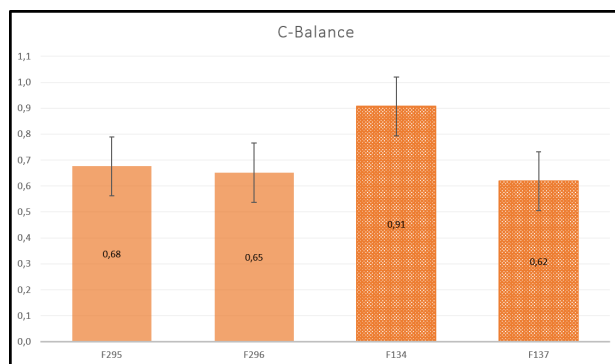

From the 10 historically performed standard fermentations, 5 were chosen to be analysed in comparison to the new standard fermentations regarding their spectral data. From those 5, 2 were compared physiologically with the 2 new standard fermentations due to deviations in the historic physiological data. Overall, an error of under 18% could be achieved for all six parameters (Table 6.1), thus the reproduction of the historic fermentations could be achieved quite well. Comparing the specific growth rate ( $\mu$  [ $h^{-1}$ ]) in Figure 6.1 and the volumetric growth rate of biomass  $r_X$  in Figure 6.5, the difference is at around 5% in between the historic (F134, F137) and new (F295, F296) standard fermentations respectively.

**Table 6.1** – Differences between the standard fermentations

	Growth Rate $\mu$	C-Balance	$\frac{CO_2}{S}$ Yield	$\frac{X}{S}$ Yield	Volumetric Growth Rate $r_X$	Substrate Uptake Rate $r_S$
	[1/h]	[-]	[C – mol/C – mol]	[C – mol/C – mol]	[C – mmol/h]	[C – mmol/h]
Average	0.01	0.71	0.32	0.39	21.30	-55.22
Standard Deviation	0.00	0.11	0.06	0.06	1.08	8.08
Difference [%]	5.11	15.92	17.17	15.04	5.08	14.63

## 6.2 Base Disturbance Fermentations

In Figures 6.7-6.12, the fermentations disturbed via missing or extensive base input (green bars, right-hand side) can be seen next to the standard fermentations (orange bars, left-hand side). Regardless of which parameter is considered, even though the fermentations were disrupted by the addition of base, they reach (almost) the same level as the ideally performed fermentations (F295, F296).

Since yeast cells must be able to adjust to the most diverse environmental conditions, a pH value that deviates from the optimal range does not automatically lead to cell death. Specifically, the enzyme  $H^+$ -ATPase, along with several systems, help to regulate the internal pH to balance out external stress. [41] To achieve this, the yeast cells in parallel must adjust their metabolism to the new environmental conditions. The cells can thus survive under these conditions and continue to process substrate, yet much of it is used on survival itself or on the metabolic change. This leads to a declining growth rate or even to a complete halt (regarding growth). Experiments showed that a pH in the strong acidic [42] and basic range [43] inhibits the metabolism of the yeast in terms of metabolic adjustments but is not necessarily lethal.

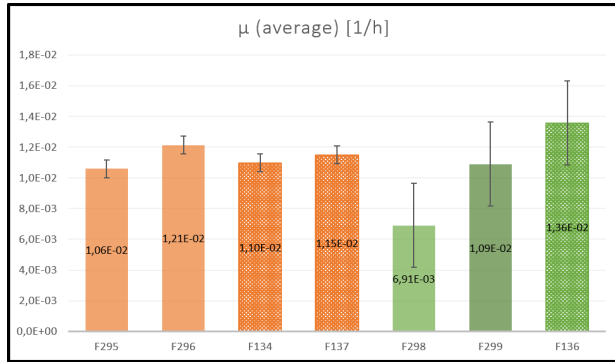

Furthermore, in experiments with a minimal substrate and biomass approach, the performed increase in base addition cannot be directly assumed to be the cause of the end of the fermentation<sup>1</sup>. In addition, the storage bottle of the base was empty just before the termination of fermentation<sup>2</sup>.

Although the two disturbances have a similar level in terms of C-balance and volumetric substrate uptake rate  $r_S$ , bigger differences can be seen in specific growth rate  $\mu$ , the  $\frac{CO_2}{S}$  Yield and the volumetric growth rate of biomass  $r_X$ . As the specific and volumetric growth rate are related, it explains their similar appearance. The lower values of *base off* (light green) compared to *base on* (dark green) could be explained by the carbon dioxide yield. It is known in literature [44, 45] that high concentrations of dissolved  $CO_2$  have an inversely proportional effect on the growth rate of yeasts. Likewise in *S.cerevisiae* an inhibition by  $CO_2$  could be determined. [46]

The increased uptake of carbon dioxide in the *base off* fermentation is most likely related to the metabolism of yeast that releases hydrogen protons into the medium when substrates are broken down. If the base that balances these protons is missing, it results in an acidic medium which may increase the interaction between the gas and the solution. The error bars represent the standard deviations in between the separate groups of fermentations (see also Table 6.2).

<sup>1</sup>Regarding the experiments in this thesis, the substrates were metabolised long before the pH levels hit a critical level concerning survival, in addition to the pH and the base consumption, the *off-gas* curves of  $O_2$  and  $CO_2$  were observed, which were used as indicators for the end of the metabolic phases.

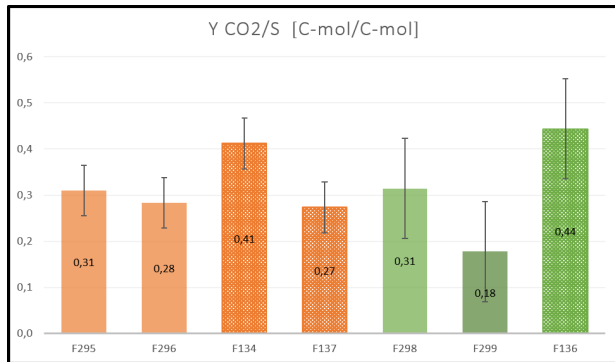

<sup>2</sup>A replacement to a new storage bottle was not possible because of the equipment provided, as this second "spare bottle" could not have been monitored by the process control system (calibration of the scales).

### 6.3 Aeration Disturbance Fermentations

While disturbances in base addition influence the yeast's operational rates, however, the yeast-preferred metabolic pathway of substrate degradation does not change fundamentally. By switching off the fumigation, the yeast changes to an anaerobic metabolism (reductive pathway), whereby the produced alcohol can no longer be processed (see 3.2.1).

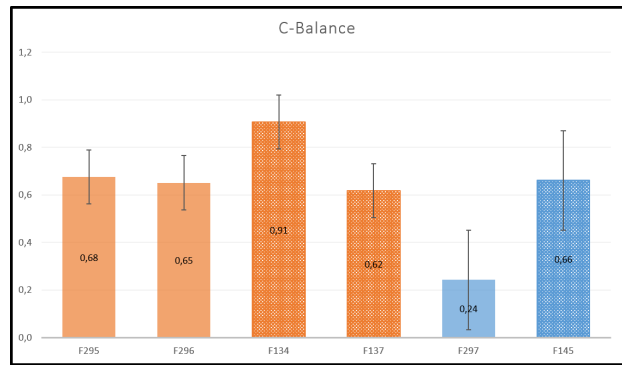

Thus, the processing of a second substrate at the end of the glucose supply is not possible and the ethanol remains unprocessed in the reactor medium. This change in raw materials can be seen in Figures 6.13-6.18, where the values for the six parameters for the disturbed *air off*-fermentation (Table 6.3) are way below the values of the standards and the *base* fermentations.

**Table 6.3** – Differences between the fermentations disturbed by aeration

	Growth Rate $\mu$	C-Balance	$\frac{CO_2}{S}$ Yield	$\frac{X}{S}$ Yield	Volumetric Growth Rate $r_X$	Substrate Uptake Rate $r_S$
	[1/h]	[-]	[C – mol/C – mol]	[C – mol/C – mol]	[C – mmol/h]	[C – mmol/h]

## 6.4 Evaluation of PCA Results

Via the software *R*, the spectral data was analysed. After the preprocessing and unifying of the data (see 5.2.3 *ff.*), the PCA results of the individual analysis and the linked data set were analysed. Those are shown in section 6.4.1 and section 6.4.2 respectively.

### 6.4.1 PCA - Individual Analysis

The new standard fermentations (Figures 6.19 and 6.20) had a steady time course of the data points over the variance of the second principal component. In the pictures, one can see a starting point in the lower right corner (dark blue), which moves into the upper right corner (light blue). The Figures 6.19-6.27 each have a dark data point in the left area. After cutting away the first 45 minutes in each record, this is the first data point to occur. Since the respective disturbances took place after 120 minutes, this data point was left in the figures to show that similar initial values were obtained at the beginning of each of the fermentations and that the trends are well visible. (All of the figures were also analysed with numbers representing sample time in order to prove the change over time.) This course of the data points is exactly the same in the data of the historical fermentations (Figures 6.21 and 6.22), although the percentage of total variance of first principal component varies significantly.

Figure 6.19 – New Standard - F295

Figure 6.20 – New Standard - F296

Figure 6.21 – Historic Standard - F134

Figure 6.22 – Historic Standard - F137

### Base Disturbance

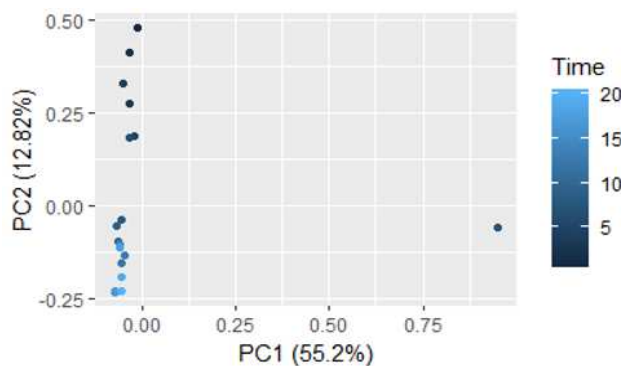

By looking at the fermentations that are disturbed by the base addition, their PCA results of the spectral data differ from the standards. At the same time, they look similar to each other (Figure 6.23 and 6.24). This may be due to the aforementioned differences in metabolism. As with the physiological data, they reach values similar to the standard fermentations, but not the same. The disturbed fermentations also start in the lower right corner and run into the upper right corner. There, however, the end is not reached as in the standards, but they move along the same axis back to their previous starting point. This course of the data points for the *base* fermentation is similar in the data of the historical fermentation (Figures 6.25)<sup>3</sup>. The changing of data over time also occurs along the second principal component and although the direction is inverted, the increasing and decreasing behaviour appears to be identically.

**Figure 6.23 –**  
New *Base off* Fermentation - F298

**Figure 6.24 –**  
New *Base on* Fermentation - F299

**Figure 6.25 –**  
Historic *Base off* Fermentation - F136

<sup>3</sup>There does not exist a recording as to when exactly the base supply was cut off in the historic fermentation which makes a comparison considerably more difficult and can be the reason for deviations.

### Aeration Disturbance

Since a change in the aeration is associated with a change in metabolism, which is fundamentally different from the standard and base fermentations, also the results of the PCA analysis look significantly different than the previous ones (Figure 6.26). As already shown with the physiological data, this difference has an effect on the yeasts and can also be seen by the evaluation of the spectral data. The data points begin at a completely different data value for the first principal component (PC1) and then develop along its axis rather than the axis of the second principal component (PC2), as in the previous figures.

**Figure 6.26 –**  
New *Air off* Fermentation - F297

**Figure 6.27 –**  
Historic *Air off* Fermentation - F145

### 6.4.2 PCA - Linked Analysis (New)

The data points aligned to the largest variance in PCA may differ significantly in their direction, depending on the origin of the data. In the previous chapter it was, for example, shown that the data from standard fermentations deviate from the disturbed ones. For the alignment of the largest variance to refer to the same properties of the data points, the next two figures show the results of this calculation (Figure 6.28 and 6.29).

As one can see in the representation by point form in Figure 6.28, all different fermentations are in a different area of the diagram. The two standard fermentations (yellow and brown) overlap each other, which represents an identical spectral recording. Each disturbed fermentation is in a section of the diagram that does not overlap with the other disturbances. Only the *air off* fermentation (green) shows a small area where it overlaps with the standard fermentations.

Figure 6.28 – Comparison of the distribution of the new fermentations regarding PCA

Using Figure 6.29, the timing of each sample shall be represented. The numbers after the letter "X" in the figure indicate the order of the data points for the respective fermentation. It can be seen that the *air off* fermentation starts with values above the standard fermentations, passes through its "cloud of data points" during the process and ends in an agglomeration below the standard fermentations. While in the "cloud of data points" in the *base off* fermentation a circular formation over time can be seen, the *base on* data points have no significant tendency into a specific direction.

Figure 6.29 – Comparison of the timely distribution of the new fermentations regarding PCA

### 6.4.3 PCA - Linked Analysis (Historic)

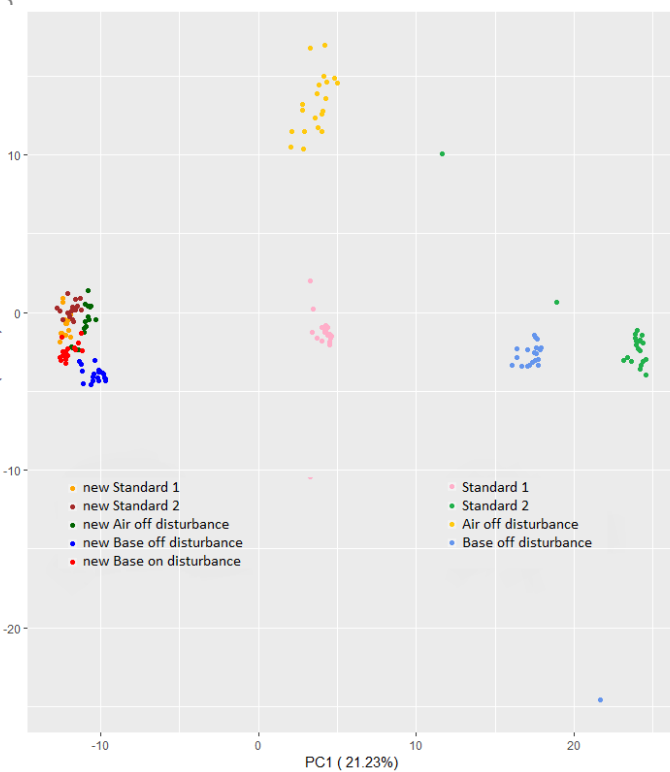

The analysis and presentation of the historical fermentations was carried out analogously to Figure 6.28. It can be seen that the two standard fermentations are clearly separated and that the data points of the base disturbed fermentation are between the two standards.<sup>4</sup> The significance of the PCA in regard of the historical fermentations should therefore be viewed critically. The proportions of the total variance for both, PC1 and PC2, are higher than those of the new fermentations in Figure 6.28.

**Figure 6.30** – Comparison of the distribution of the historic fermentations regarding PCA

<sup>4</sup>In order to be able to display the data points as good as possible, one data point of fermentation F137 (Standard 2) was removed (coordinates at about 10/-20).

In order to be able to compare the informational value of the spectral data of the analysis, a PCA analysis was carried out over the entire data (new and historic fermentations). The data points of the new and historical fermentations are shown in Figure 6.31a and 6.31b. The new fermentations (F295 - F299) overlap on the left in those illustrations. The historical fermentations show a similar distribution as in Figure 6.30 and it can be seen that the axis - on which the two standard and the base disturbed fermentation are distributed on - is also present in this figure (although slightly turned). The air disturbed fermentation (F145, yellow) lies vertically above the standard fermentation F134 (rose). This becomes even clearer when looking at Figure 6.31b, where the PC1 is plotted against the PC3. The two fermentations, prior lying vertically one above the other, now overlap and in turn - again - form an axis with the other two historical fermentations. This leads to a further reason for the assumption that a better classification of the fermentations could be made on higher PCs. This assumption was checked up to the fifth principal component, but no improvement was shown. It can also be seen in Figure 6.31b that the "cloud of data points" of the new fermentations is now divided as the *base-off* fermentation lies "above" the others. Its data points are now at around the same values of PC3 as the historical *base-off* fermentation.

(a) Comparison of the new and historic fermentations regarding PC1 and PC2

(b) Comparison of the new and historic fermentations regarding PC1 and PC3

**Figure 6.31** – Results of the PCA analysis with linked fermentations (new and historic)

# Chapter 7 - Conclusion

## Offline Data

The physiological data - on which the comparison of the new with the historical data was based - showed great similarity between the individual fermentations (standard vs. standard, base vs. base, air vs. air). In particular, the standard fermentations showed great similarity when compared to their historical counterparts. The growth rate for instance showed a difference of just over five percent. As already described in the text above (see 6.1), only two of the ten fermentations carried out in 2016 were compared with the new standards. This was due to the standard fermentations containing certain temporal and operational fluctuations in their data. During the preparation of the spectral data of these fermentations, large outliers in the middle of the fermentations were found which is why only two fermentations were ultimately used as a comparison with the new ones.

With the fermentations disturbed by the base, it could be shown that a disturbance in the pH value seems to have only marginal effects on the metabolism, when considering the total batch time. Slightly different values could be found in the fermentations. In order to be able to make more precise statements for these analyses, however, further fermentations under the same conditions are necessary. Unfortunately, no fermentation was carried out in 2016 in which the base was added uncontrolled. As a result, no exact comparison could be made, which means that the standard deviations of the base fermentations are significantly higher than those of the standard fermentations.

The fermentations in which the air supply was cut off showed the difference in metabolism more clearly. The large deviations of the new fermentations from the historical fermentations are mainly due to the changing equipment with the different oxygen and exhaust gas sensors. Here, too, further fermentations would have to be carried out, so that a tendency can be inferred.

## On-line Analysis

### Individual PCA Analysis

When processing and analysing the spectral data with the software, similarities to the off-line data could be determined. The results of the PCA of the standard fermentations shown in Figure 6.19 - 6.22 are very similar both to each other and with their historical counterparts. Time dependent behaviour can be seen in all fermentations and a distinction can be made between the individual variants of the implementation. Nevertheless, the fermentation data was processed individually in this analysis and not on a combined level. Even if the same trends can be identified, they can occur differently (in their variance), as can also be seen in the base fermentations (see Figure 6.23 - 6.25).

### Linked PCA Analysis

The analysis using PCA with simultaneous calculation of the variance shows that a clear distinction can be made between the new fermentations in the first two principal components (see Figure 6.28). The standard fermentations overlap, which can be seen as an argument for reproducibility and at the same time they clearly differentiate from the disturbances.

The historical fermentations can also be clearly distinguished, but the standards are not as close together to each other as the new ones. It can only be assumed what this lack of reproducibility of the historical standards can be attributed to. It is possible that there are clear differences between these two fermentations for PCA even if these were not recognized during the initial selection for physiological consideration and when the spectral data sets were first analysed. With regard to the distribution of the data points of the historical fermentations, it should be noted that:

- i) When considering the first and third principal components, the two *base-off* fermentations are at approximately the same value for the third principal component.
- ii) When comparing the first and third principal components, the four historic fermentations lie on one axis, which can be traced back to an origin that has not yet been found.

### 1<sup>st</sup> Scientific Question

*Can spectral data capture deviations in metabolic states in yeast in low concentrations?*

The spectral data associated with the physiological data showed a distinction between the two metabolic states of yeast (anaerobic / aerobic). It was also possible to differentiate between high and low pH of the medium using spectral data. Thus, yeast disorders are also recognizable, which are associated with a change in metabolism, but not due to changes from aerobic to anaerobic, but from an optimal pH value environment to suboptimal conditions. The monitoring of metabolic state could be useful while inoculating during scale up from a prior small volume (e.g. shaking flasks). Especially in early stages the yeast should be transferred within its exponential growth rate to adjust best to new surrounding media as the majority of the existing enzymes in the yeasts are used for growth. If the state of the microorganisms can be defined, the right time for transfer could be chosen more accurately. Although industrial processes work with a much higher cell densities, part of this study was to establish and develop workflows within the laboratory the study was performed. Additionally, the historic data had to be reconstructed as similar as possible and therefore the processes were conducted with lower cell density levels.

## 2<sup>nd</sup> Scientific Question

*Are the deviations distinguishable from each other within PCA analysis?*

Comparing new and historic fermentation data, no exact statement can be given. The historic data lets one differentiate between optimum and disturbance, but the standard fermentations do not overlap. If the standards are not reproducible, the significance of the deviation of the disturbances must be viewed critically. This deviation of standards may be due to the conversion of the old data, as this fermentation was carried out with other devices (see 5.2). In general, there are not enough measurements for the disturbed fermentations to test how they can be reproduced with each other. It can be shown by the combined PCA that the new fermentations and the historical ones differ greatly in terms of the first three principal components. Likewise, no reproduction between the individual counterparts (standard vs. standard, base vs. base, air vs. air) can be shown.

Nevertheless, the new standard fermentations are comparable with each other. The data points of the historic standard fermentations are "shifted" locally, but they have a very similar appearance. An analysis of the time dependency of the data points also showed a very large agreement with a counterclockwise course during the fermentation (see Figure 7.1) which can be seen when magnifying the two standards from Figure 6.30. The physiological comparison led to an error of maximum 18% in the standard fermentations based on the six criteria tested. Depending on spectral data, the deviations are much bigger and need more data to see a trend for reproducibility.

(a) Zoom on the data of F134

(b) Zoom on the data of F137  
(The data points of F136 can be neglected)

**Figure 7.1** – Time dependent behaviour of the historic standard fermentations

## Chapter 8 - Outlook

The new fermentations showed a good approach to record the metabolic states of yeast in a bioreactor using spectral data. The individual runs could be differentiated from each other and the off-line measurements showed results that supported the on-line records in relation to the metabolism states. The next big step has to be a further implementation of fermentations of the same structure so that more data is available, which can be compared to the already known data and results. With more data, not only can previous assumptions be confirmed with greater accuracy, but also a better basis for modelling is formed.

The creation of a model on the basis of the data obtained could lead to early detection of errors that are discovered through on-line monitoring. This would improve the response time to unexpected disturbances. The model could thus be expanded by additional statistical methods such as PLS or Hotelling  $T^2$ , which enables the data to be examined more closely. Furthermore, the off-line data (sampling) was taken at large intervals during the processes (about every 2 hours). The time intervals between sampling could be reduced to check whether the time trend could be improved. If this is the case, one would have an even finer tool for finding deviations in a minimal period of time. In addition to larger amounts of data and increased methods of statistics to investigate them, operational improvements could also be made.

During handling with the light guide, which was installed via the lid, deviations in the spectra could be determined, which were due to the winding path of the light guide to the reactor, which could not be reproduced exactly from fermentation to fermentation. The use of a reactor that would allow the light guide to be installed horizontally from the side would be one possibility of change. It would be questionable whether the same measurement results would be obtained at minimal biomass concentrations through the glass wall or whether the absorption of / transmission through the glass is a problem.

In addition to collecting data regarding batch fermentations, records of fed-batch processes would also have to be planned in order to detect any changes due to the addition of substrate/s. Fed-batch processes are also used more frequently in industry than batch processes, which means that modelling could be applied to a wider range of processes.

# Chapter 9 - Appendix

## 9.1 List of Equipment

### 9.1.1 Chemicals and Yeast

#### Chemicals

All chemicals used for media and stock solutions are found in Table 5.1 and 5.2.

The antifoam agent used was *Struktol J673*.

*NaOH* was used as base to control the pH and in the *base-on* fermentation to disturb the optimum. All chemicals were purchased via *LACTAN* in highest quality.

#### Yeast Strain

The microorganism used in this thesis is a yeast strain of *Saccharomyces cerevisiae* that is used (and cultivated) by "*HAGOLD Hefe GmbH*", part of "*LALLEMAND Inc.*". Since the information on the yeast strain is subject to industrial secrecy, no statement can be made for the exact determination of the strain. For further calculation a biomass of 26.9 g/C-mol (with a composition of  $CH_{1.769}N_{0.146}O_{0.631}$ ) has been used according to *Lange et al.* [47].

### 9.1.2 Bioreactor and Instruments

The instruments used during the processes are listed in Table 9.1 and the placement can be seen in Figure 9.1.

**Figure 9.1** – Mounting positions of the devices on the bioreactor cover

**Table 9.1** – Type designations and description of the connected devices

Position	Description	Type Designation
A	cooling finger	/
B	pO <sub>2</sub> probe to monitor the oxygen partial pressure in the medium	Hamilton VisiFerm DO Arc 325
C	off-gas cooler with outlet for excess gas of the fermentation broth	/
D	Hamilton-Incyte probe for in-line determination of biomass	Hamilton Pre-Amp 243720
E	connection for 4-way access (addition of acid, base and/or feed)	/
F	ventilation hose for introducing air into the medium	/
G	pH probe that measures both pH and temperature	Hamilton EasyFerm HB Arc 225
H	tube for taking samples	/
I	inlet for the NIR probe	StellarNet BLACK-Comet CXR-SR-25 spectrometer
J	motor of the stirrer	/

## 9.2 R Code

Please note that the colour settings for graphic illustrations in code functions may differ from the actual used ones within this thesis as they have been changed in the illustrations afterwards due to better visibility in printed versions.

# List of Tables

5.1	Weighted amount of the ingredients of medium, substrate (glucose) and biomass for the six standard fermentations (F295 - F299) . . . . .	18
5.2	Ingredients of the trace elements stock solution . . . . .	19
6.1	Differences between the standard fermentations . . . . .	24
6.2	Differences between the fermentations disturbed by base . . . . .	28
6.3	Differences between the fermentations disturbed by aeration . . . . .	28
9.1	Type designations and description of the connected devices . . . . .	43

# List of Figures

3.1	Sampling locations in processes [10] . . . . .	5
3.2	Respiratory capacity in <i>bottleneck</i> -representation (green ring); adapted from [16] The arrows indicate substrates glucose (orange) and ethanol (blue) in three metabolic states . . . . .	8
3.3	Electromagnetic spectrum with its respective influence on electrons [10] . . . . .	10
3.4	Areas of NIR spectroscopy application in bioprocesses; adapted from [4] (1- commonly used; 2- utility proven at lab scale; 3- utility under investigation)	11
6.1	Comparison of the growth rate $\mu$ . . . . .	25
6.2	Comparison of the C-balance . . . . .	25
6.3	Comparison of the carbon dioxide yield . . . . .	25
6.4	Comparison of the biomass yield . . . . .	25
6.5	Comparison of the volumetric growth rate of biomass $r_X$ . . . . .	25
6.6	Comparison of the volumetric substrate uptake rate $r_S$ . . . . .	25
6.7	<i>Base</i> disturbances: Comparison of the growth rate $\mu$ . . . . .	27
6.8	<i>Base</i> disturbances: Comparison of the C-balance . . . . .	27
6.9	<i>Base</i> disturbances: Comparison of the carbon dioxide yield . . . . .	27
6.10	<i>Base</i> disturbances: Comparison of the biomass yield . . . . .	27
6.11	<i>Base</i> disturbances: Comparison of the volumetric growth rate of biomass $r_X$	27
6.12	<i>Base</i> disturbances: Comparison of the volumetric substrate uptake rate $r_S$ .	27
6.13	<i>Air off</i> disturbance: Comparison of the growth rate $\mu$ . . . . .	29
6.14	<i>Air off</i> disturbance: Comparison of the C-balance . . . . .	29
6.15	<i>Air off</i> disturbance: Comparison of the carbon dioxide yield . . . . .	29
6.16	<i>Air off</i> disturbance: Comparison of the biomass yield . . . . .	29
6.17	<i>Air off</i> disturbance: Comparison of the volumetric growth rate of biomass $r_X$	29
6.18	<i>Air off</i> disturbance: Comparison of the volumetric substrate uptake rate $r_S$	29
6.19	New Standard - F295 . . . . .	30
6.20	New Standard - F296 . . . . .	30
6.21	Historic Standard - F134 . . . . .	30
6.22	Historic Standard - F137 . . . . .	30
6.23	New <i>Base off</i> Fermentation - F298 . . . . .	31
6.24	New <i>Base on</i> Fermentation - F299 . . . . .	31
6.25	Historic <i>Base off</i> Fermentation - F136 . . . . .	31
6.26	New <i>Air off</i> Fermentation - F297 . . . . .	32
6.27	Historic <i>Air off</i> Fermentation - F145 . . . . .	32
6.28	Comparison of the distribution of the new fermentations regarding PCA . . . . .	33
6.29	Comparison of the timely distribution of the new fermentations regarding PCA	34
6.30	Comparison of the distribution of the historic fermentations regarding PCA .	35
6.31	Results of the PCA analysis with linked fermentations (new and historic) . .	36
7.1	Time dependent behaviour of the historic standard fermentations . . . . .	40

9.1 Mounting positions of the devices on the bioreactor cover . . . . . 43
