ABSTRACT
Most work on query optimization has concentrated on loop-free queries. However, data science and machine learning workloads today typically involve recursive or iterative computation. In this work, we propose a novel framework for optimizing recursive queries using methods from program synthesis. In particular, we introduce a simple yet powerful optimization rule called the “FGH-rule” which aims to find a faster way to evaluate a recursive program. The solution is found by making use of powerful tools, such as a program synthesizer, an SMT-solver, and an equality saturation system. We demonstrate the strength of the optimization by showing that the FGH-rule can lead to speedups up to 4 orders of magnitude on three, already optimized Datalog systems.

1 INTRODUCTION
Most database systems are designed to support primarily non-recursive (loop-free) queries. Their optimizers are based on the rule-driven, cost-based Volcano architecture, designed specifically for optimizing non-recursive query plans. However, most data science and machine learning workloads today involve some form of recursion or iteration. Examples include finding the connected components of a graph, computing the page rank, computing the network centrality, minimizing an objective function using gradient descent, etc. The importance of supporting recursive queries has been noted by system designers. Some modern data analytics systems, like Spark or Tensorflow, support for-loops. The SQL standard defines a limited form of recursive queries, using the WITH construct, and some popular engines, like Postgres or SQLite, do support this restricted form of recursion.

Datalog is a language designed specifically for recursive queries, and it is gaining in popularity [3, 12, 14, 22, 35, 37, 38, 48, 49]. But the optimization problem for recursive queries is much less studied. A datalog program consists of multiple rules, defining several, mutually recursive relations, and one distinguished relation name which is the output of the program. The effect of the program consist of repeatedly applying the rules, sometimes called the body of the program, until a fixpoint is reached, then it returns the output relation. Datalog engines typically optimize the loop body, without optimizing the actual loop. The few systems that do, apply only limited optimization techniques, like magic set optimization and semi-naive evaluation, which are restricted to positive queries.

In this paper we describe a new query optimization framework for recursive queries. Our framework replaces a recursive program with another, equivalent recursive program, whose body may be quite different, and thus focuses on optimizing the recursive program as a whole, not on optimizing its body in isolation; the latter can be done separately, using standard query optimization techniques. Our optimization is based on a novel rewrite rule for recursive programs, called the FGH-rule, which we implement using program synthesis, a technique developed in the programming languages and verification communities. We introduce a new method for inferring loop invariants, which extends the reach of the FGH-rule, and also show how to use global constraints on the data for semantic optimizations using the FGH-rule.

The FGH-Rule At the core of our approach is a novel, yet very simple rewrite rule, called the FGH-rule (pronounced fig-rule), which can be used to prove that two recursive programs are equivalent, even when their loop bodies are quite different. We show that the FGH-rule can express previously known optimizations for Datalog, including magic sets and semi-naive evaluation, and also a wide range of new optimizations. The optimized program is often significantly more efficient than the original program, and sometimes can have a strictly lower asymptotic complexity. We implemented a source-to-source optimizer using the FGH-rule, evaluated its effectiveness on several Datalog systems, and observed speedups of up to 4 orders of magnitude (Sec. 8).
where every candidate query rewriting is guaranteed to be correct, which is a technique designed for program sketching. A verifier also produces a small counterexample database for each query, where every node \( L(x) \) is the minimum of its own label and the smallest CC label of its neighbors, using a single recursive rule with min-aggregation. The space complexity of the transitive closure is \( O(n^2) \), which, in practice, is prohibitively expensive on large graphs. On the other hand, the optimized query has space complexity \( O(n) \).

**Pattern Matching vs. Query Synthesis** Applying the FGH-rule is an instance of query rewriting using views. In that problem we are given a set of view expressions and a query, and the task is to write the query to use the view expressions rather than the base relations. This problem has been extensively studied in the literature [21], and today’s database systems perform it using pattern matching [16]. This is a form of transformational synthesis, where every candidate query rewriting is guaranteed to be correct, because it is obtained by applying a limited set of manually crafted rules (patterns), which are guaranteed to be correct. However, the FGH-rule often requires exploring a very large space, which cannot be covered by a limited set of rules. In this paper we propose to use counterexample-guided inductive synthesis (CEGIS) for this purpose, which is a technique designed for program synthesis [43, 46]. When applied to our context, we call this technique query synthesis. Unlike pattern matching, query synthesis explores a much larger space, by examining rewritings that are not necessarily correct, and need to be checked for correctness by a verifier (23 in our system). The verifier also produces a small counterexample database for each rejected candidate, and these counterexamples are collected by the synthesizer and used to produce only candidate rewritings that pass all the previous counterexamples, which significantly prunes the search space of the synthesizer. We report in Sec. 8 synthesis times of less than 1 second, even for complex queries that use global constraints and require inferring loop invariants.

**Monotone Queries and Semiring Semantics** Datalog is, by definition, restricted to monotone queries. This ensures that every query has a well-defined semantics, namely the least fixpoint of its immediate consequence operator. Existing optimizations for Datalog, like semi-naive evaluation and magic set rewriting, apply mainly to monotone queries. Even stratified negation can (if at all) only be handled by imposing appropriate restrictions [44]. But queries that contain aggregates or negation (expressed in SQL via subqueries) are not monotone, and most systems that support recursion prohibit the combination of aggregates and recursion. This has two shortcomings: it limits what kind of queries the user can express, and also prevents many of our FGH-rewritings. For example, the simple computation of connected components in Fig. 1 (a) can be expressed in PostgreSQL, or in SQLite, or in Soufflé, because the first rule uses only recursion and the second rule uses only aggregation. However, none of these systems accepts the query in Fig. 1 (b), because it combines recursion and aggregation. In order to express such queries, in this paper we propose an extension of Datalog, following the approach in [18], where the relations are interpreted over ordered semirings.

A semiring is an algebraic structure with two operations, +, ⊗. Traditional Datalog corresponds to the Boolean semiring, where these two operators are ∧, ∨, while the query in Fig. 1 (b) is over the Tropical semiring, where the two operators are min, + (reviewed in Sec. 2). We call this extension of Datalog to ordered semirings Datalog\(^o\), pronounced “Datalogo”, where the circle represents the semiring. In Datalog\(^o\) recursion is still restricted to monotone\(^o\) queries, but monotone queries in Datalog\(^a\) include queries with aggregates, over an appropriate semiring. The query in Fig. 1 (b) is monotone over the (ordered) tropical semiring.

**Loop Invariants** One difficulty in reasoning about loops in programming languages is the need to discover loop invariants. Some (but not all) applications of the FGH-rule also require the discovery of loop invariants. We describe a novel technique for inferring loop invariants for Datalog\(^o\) programs, by combining symbolic execution with equality saturation, and using a verifier. We execute symbolically the recursive program for a very small number of iterations (five in our system), obtain query expressions for the IDBs (the recursive predicates), and construct all identities satisfied by the IDBs. Then, we retain only candidates that hold at each iteration, and check each candidate for correctness using the SMT solver. By inferring and using loop invariants we show that we can significantly improve some instances of magic-set optimizations from the literature: we call the new optimization beyond magic.

**Constraints and Semantic Optimizations** Optimizations that are conditioned on certain constraints on the database are known as semantic optimizations [32]. SQL optimizers routinely use key constraints and foreign key constraints to optimize queries. More powerful optimizations can be performed using the chase and backchase framework [10, 30], and these include optimizations under inclusion constraints, or conditional functional dependencies, or tuple generating constraints. However, all constraints that are useful for optimizing non-recursive queries are local. In contrast, the FGH-rule optimizes recursive queries, and therefore it can also exploit global constraints. For example, suppose the database represents a graph, and the global constraint states that the graph is a tree. This global constraint does not help optimize non-recursive queries, but can be used to great advantage to optimize some recursive queries; we give details in Sec. 3.3.

---

1. Prior work [15, 37] has proposed extending Datalog with min and max aggregates by explicitly re-defining the semantics of recursive rules with aggregates. Our approach keeps the standard least fixpoint semantics, but generalizes the semiring.
2. This monotonicity is over the partial order from the ordered semiring.
Equality Saturation Systems

Throughout our optimizer we need to manage symbolic expressions of queries, and their equivalence classes, as defined by a set of rules. We use for this purpose a state-of-the-art Equality Saturation System (EQSAT), EGG [53]. We show how to use EQSAT for checking equality under constraints, inferring loop invariants, and “denormalization” (which is essentially query rewriting using views).

Related Work

Our work was partially inspired by the PreM condition, described by Zaniolo et al. [54], which, as we shall explain, is a special case of the FGH-rule. Unlike our system, their implementation required the programmer to check the PreM manually, then perform the corresponding optimization. Several prior systems leveraged SMT-solvers to reason about query languages [8, 19, 36, 47, 50]; but none of these consider recursive queries. Datalog synthesizers have been described in [2, 31, 41, 42, 51]. Their setting is different from ours: the specification is given by input-output examples, and the synthesizer needs to produce a program that matches all examples. A design choice that we made, and which sets us further aside from the previous systems, is to use an existing CEGIS system, Rosette; thus, we do not aim to improve the CEGIS system itself, but optimize the way we use it.

Contributions

In summary, the main contribution of this paper consists of a new, principled and powerful method for optimizing recursive queries. We make the following specific contributions:

- We introduce a simple optimization rule for recursive queries, called the FGH-rule (Sec. 3).
- We show the FGH-rule captures known optimizations (magic sets, PreM, semi-naive), (Sec. 3.1), new optimizations (Sec. 3.2), and optimizations under global constraints (Sec. 3.3).
- We present our novel framework for query optimization via the FGH-rule (Sec. 4).
- We describe how an SMT solver (Sec. 5) and a CEGIS system (Sec. 6) can be profitably integrated into our FGH-optimizer.
- We describe how to use an EQSAT system for various tasks in the FGH optimizer: loop-invariant inference, denormalization, and checking equivalence under constraints (Sec. 7).

2 BACKGROUND

Datalog

A relation of arity $k$ is a finite subset of $D^k$, where $D$ is a fixed domain. The abbreviations EDB and IDB stand for Extensonal Database and Intensional Database, and represent the base relations and the computed relations respectively. A rule has the form:

$$R_0(vars) :- R_1(vars_1) \land \cdots \land R_m(vars_m)$$

where $R_0$ is an IDB, and $R_1, \ldots, R_m$ are IDBs or EDBs. The rule is safe if every variable occurs in at least some predicate in the body, and the rule is linear if its body contains at most one IDB. A Datalog program consists of a set of possibly mutually recursive rules. Usually, only a subset of the IDB predicates are returned to the user, and we will call them the answer IDBs. The Immediate Consequence Operator, ICO, is the mapping on the IDB predicates that consists of one application of all the Datalog rules. The semantics of a Datalog program is given by the least fixpoint of its ICO. The naive evaluation algorithm consists of repeatedly applying the ICO until the IDBs no longer change.

In this paper we will combine multiple rules with the same head into a single rule by OR-ing their bodies, and writing explicitly all existential quantifiers. This is a common convention used in the literature, see e.g., [13]. For example the following datalog program, which computes the transitive closure of a relation $E$,

$$TC(x, y) :- E(x, y)$$
$$TC(x, y) :- E(x, z) \land TC(z, y)$$

becomes $TC(x, y) :- E(x, y) \lor \exists z(E(x, z) \land TC(z, y))$.

(Pre-)Semirings

A pre-semiring is a tuple $S = (\mathcal{B}, \emptyset, \otimes, \ominus, \mathcal{E}, \mathcal{F})$ where $\otimes$ is commutative, both $\emptyset, \ominus$ are associative, have identities $\emptyset$ and 1 respectively, and $\otimes$ distributes over $\emptyset$. When $\otimes$ is commutative, then we call $S$ a commutative pre-semiring. All pre-semirings in this paper are commutative, and we will simply refer to them as pre-semirings. When the equality $x \otimes \emptyset = \emptyset$ holds for all $x$, then it is called a semiring. An ordered pre-semiring is a pre-semiring with a partial order $\preceq$, where both $\emptyset, \ominus$ are monotone operations. When the partial order is defined by $x \preceq y$ iff $\exists z, x \otimes z = y$ then it is called the natural order. Examples of ordered (pre-)semirings are the Booleans $\mathcal{B} = (\{0,1\}, \lor, \land, \ominus, \emptyset)$, the closed natural numbers $\mathbb{N}_\infty = (\mathbb{N} \cup \{\infty\}, +, *, 0, 1)$, the tropical semiring $\text{Trop} = (\mathbb{N} \cup \{\infty\}, \min, +, \ominus, 0, 1)$, the reversed tropical semiring $\text{Trop}^R = (\mathbb{N}, \max, +, 0, 0)$, the lifted naturals and lifted reals $\mathbb{N}_L = (\mathbb{N} \cup \{\bot\}, +, *, 0, 1)$, $\mathbb{R}_L = (\mathbb{R} \cup \{\bot\}, +, *, 0, 1)$, where $\bot = x = \top$. The structures $\mathcal{B}, \mathbb{N}_\infty$, $\text{Trop}$ are semirings, the others are pre-semirings. $\mathbb{B}, \mathbb{N}_\infty$, $\text{Trop}$, and $\text{Trop}^R$ are naturally ordered. Confusingly (!), the order relation on $\text{Trop}$ is the reverse one: $\infty$ is the smallest, and 0 is the largest element. The order relation in $\mathbb{N}_L$ and $\mathbb{R}_L$ is given by $\bot \leq x$ for all $x$: they are ordered pre-semirings but not naturally ordered.

$S$-relations

An $S$-relation $R$ is a function that associates to each tuple $t \in D^k$ a value in the semiring, $R[t] \in S$. In this context, $S$ is called the value space of the relation $R$, while the domain $D$ of its attributes is called the key space. $S$-relations were first introduced\footnote{Note that we define $\text{Trop}$ and $\text{Trop}^R$ over the natural numbers rather than the reals. The motivation for this slight deviation from the standard definition of these semirings will become clear in Section 5: the support of integer theories by the SMT-solver z3.} by Green et al. [18] in order to model data provenance. A $\mathcal{B}$-relation is a set, an $\mathbb{N}_\infty$-relation is a bag (with possibly infinite multiplicities), an $\mathbb{R}_L$-relation is a tensor (with possibly undefined entries).

Queries

Consider a relational schema $R_1, R_2, \ldots$ over a pre-semiring $S$. A positive (relational algebra) query is a relational algebra expression using selections, projections, joins, and unions (no difference operator in the positive fragment). The most common definition of the relational algebra restricts the predicates used in selections to equality predicates, $x = y$. In this paper we follow [18] and allow arbitrary predicates $p(x, y, \ldots)$ over the value space, including disequality $x \neq y$, inequality $x < y$, or any other interpreted predicate. Green [18] showed that positive relational algebra extends naturally to an arbitrary semiring $S$. When $S$ is the Boolean semiring, then this coincides with the set semantics of relational algebra, and when $S$ is the semiring of natural numbers, then it coincides with bag semantics.
Normal Forms

Alternatively, a query can be described using rules, as follows. A sum-product query has an expression

\[ T(x_1, \ldots, x_k) : \bigoplus_{x_{k+1}, \ldots, x_m \in D} A_1 \otimes \cdots \otimes A_m \]  

where each \( A_i \) is a relational atom of the form \( R_i(x_{i_1}, \ldots, x_{i_{k_i}}) \), or some interpreted predicate such as \( x_i > 5x_j + 3 \). The variables \( x_1, \ldots, x_k \) are called free variables, or head variables, and the others are called bound variables. A sum-sum-product query has the form:

\[ Q(x_1, \ldots, x_k) : T_1(x_1, \ldots, x_k) \oplus \cdots \oplus T_q(x_1, \ldots, x_k) \]  

where \( T_1, T_2, \ldots, T_q \) are sum-product expressions with the same head variables \( x_1, \ldots, x_k \). When the semiring is \([0, \infty)\) and the interpreted predicates are restricted to equality predicates, these queries are (Unions of) Conjunctive Queries (UCQs) under set semantics; when the semiring is \([\mathbb{R}, \leq]\), the sum-products are tensor expressions, sometimes called Einsum expressions [34].

Every positive relational algebra query \( Q \) can be converted into a sum-sum-product expression, which we call the normal form of \( Q \).

Datalog\textsuperscript{\textcopyright}

Let \( S \) be an ordered pre-semiring. A Datalog\textsuperscript{\textcopyright} program consists of a set of (possibly recursive) sum-sum-product rules (2) over \( S \)-relations. We allow two extensions to the expressions (1) and (2): the summation in (1) may be restricted by some Boolean predicate, and we also allow an atom \( A \) in (1) to be an interpreted function. One important interpreted function is the cast operator \([-]_0^1 : \mathbb{B} \rightarrow S \), which maps 0 to \( \hat{0} = 1 \) and \( 1 \) to \( \hat{1} \) and therefore, for any predicate \( P \), \([P]_{\hat{0}} \hat{1} \) is an atom in the pre-semiring \( S \). For example, \([x < y]_{\hat{0}} \hat{1} \) is \( \hat{0} \) when \( x \geq y \) and \( \hat{1} \) when \( x < y \); when \( \hat{0}, \hat{1} \) are clear from the context, we drop them and write simply \([x < y]\). We treat interpreted functions in a similar way to negation in standard Datalog, and require a program to be stratified, such that the interpreted functions are applied only to EDBs or to IDBs defined in earlier strata. This implies that the ICO of that stratum is a monotone function in the IDBs defined by that stratum, and its semantics is defined as its least fixpoint. Abo Khamis et al. [23] proved that any Datalog\textsuperscript{\textcopyright} program over the semirings discussed in this section (except for \([0, \infty)\) and \([0, \infty)\)) converges in polynomial time in the size of the input database.

Example 2.1. Consider the body of the rule in Fig. 1(b). The relations \( L, CC \) are over the tropical semiring, while \( E \) is over the Boolean semiring. Formally, its body is a sum-sum-product expression, with a Boolean predicate:

\[ L[x] \oplus \bigoplus_{y} (CC[y] \otimes E(x, y)) \]

Here the summation \( \bigoplus_{y} \) is restricted to those values \( y \) that satisfy the predicate \( E(x, y) \). Equivalently, we can rephrase it as:

\[ L[x] \oplus \bigoplus_{y} (CC[y] \otimes E(x, y))_{\hat{0}} \]

where \( [\cdot]_{\hat{0}} \) is the cast operator from \( \mathbb{B} \) to trop; it maps \( 0, 1 \) to \( \hat{0}, \hat{1} \) respectively. Alternatively, suppose that we represent a label \( o = L(x, o) \) using a standard, Boolean-valued relation \( L(x, o) \), where \( x \) is a key, and \( o \) is the numerical value (label). Then, instead of the atom \( L(x) \) we would write \( \bigoplus_o \{ o \mid L(x, o) \} \), or \( \bigoplus_o \{ o \otimes [L(x, o)]_{\hat{0}} \} \). Here \( o \) is considered to be an atom.

3 THE FGH-RULE

In this section we introduce a simple rewrite rule that allows us to rewrite an iterative program to another, possibly more efficient program. Then, we illustrate how this rule, when applied to Datalog\textsuperscript{\textcopyright} programs, can express several known optimizations in the literature, as well as some new ones.

Consider an iterative program that repeatedly applies a function \( F \) until some termination condition is satisfied, then applies a function \( G \) that returns the final answer \( Y \):

\[ X \leftarrow X_0 \]
\[ 1 \text{loop } X \leftarrow F(X) \text{ end loop} \]
\[ Y \leftarrow G(X) \]

We call this an FG-program. The FGH-rule (pronounced FIG-rule) provides a sufficient condition for the final answer \( Y \) to be computed by the alternative program, called the GH-program:

\[ Y \leftarrow G(X_0) \]
\[ 1 \text{loop } Y \leftarrow H(Y) \text{ end loop} \]

Theorem 3.1 (The FGH-Rule). If the following identity holds:

\[ G(F(X)) = H(G(X)) \]

then the FG-program (3) is equivalent to the GH-program (4).

Proof. Let \( X_0, X_1, X_2, \ldots \) denote the intermediate values of the FG-program, and \( Y_0, Y_1, Y_2, \ldots \) those of the GH-program. By the FGH-rule, the following diagram commutes, proving the claim:

\[ \begin{array}{c}
X_0 \xrightarrow{F} X_1 \xrightarrow{F} X_2 \xrightarrow{\cdots} X_n \\
Y_0 \xrightarrow{H} Y_1 \xrightarrow{H} Y_2 \xrightarrow{\cdots} Y_n
\end{array} \]

In this paper we will apply the FGH-rule to optimize Datalog\textsuperscript{\textcopyright} programs. In this context, \( F \) is the ICO of the Datalog\textsuperscript{\textcopyright} program, \( X \) is the tuple of all its IDB predicates, and \( Y \) are the answer-IDB predicates. We will also make the natural assumption that \( G \) maps the initial state \( X_0 \) of the IDBs of the program (3) to the initial state \( Y_0 \) of (4). For example, if both programs are traditional Datalog programs, then the initial state consists of all IDBs being the empty set, which we denote, with some abuse, by \( X_0 = \emptyset \), even when \( X \) consists of several mutually recursive IDBs. Similarly, \( Y_0 = \emptyset \).

Typically, \( G \) is a conjunctive query, which maps \( \emptyset \) to \( \emptyset \), and in that case the theorem implies that, if Eq. (5) holds, then the following Datalog\textsuperscript{\textcopyright} programs \( \Pi_1, \Pi_2 \) return the same answer \( Y \):

\[ \Pi_1 : \quad X \leftarrow F(X) \quad \Pi_2 : \quad Y \leftarrow H(Y) \quad Y \leftarrow G(X) \]

More generally, however, the theorem does not care about the termination condition of the FG-programs (3). It only assumes that the GH-program is executed the same number of iterations as the FG-program. However, it follows immediately that, if \( F \) reaches a fixpoint, then so does \( H \):

Corollary 3.2. If the FG-program reaches a fixpoint after \( n \) steps (meaning: \( X_n = X_{n+1} \) then the GH-program also reaches a fixpoint.
The three transformations $y$ variables optimizer significantly, it also limits the type of optimizations that $H$ and the $FGH$-rule holds. The $simpler ICO$. The $mappability$ target of query optimization in the literature, see e.g., [55]. The $of the connected components of a graph, which is a well-known $3.1 Simple Examples$

Example 3.5 (Simple Magic). The simplest application of magic set optimizations. We check that (7) is equivalent to (8) by verifying the $FGH$-rule. The functions $F, G, H$ are shown in Fig. 3. One can verify that $G(F(TC)) = H(G(TC))$, for any relation $TC$. Indeed, after converting both expressions to normal form, we obtain $G(F(TC)) = H(G(TC)) = P$, where:

\[ P(y) \overset{\text{def}}{=} \{ y = a \} \lor \exists z(Q(z) \land E(z, y)) \]

We prove in the full version of this paper that, given a sideways information passing strategy (SIPS) [6] every magic set optimization [4] over a Datalog program can be proven correct using a sequence of applications of the $FGH$-rule.

Example 3.6 (Generalized Semi-Naive Evaluation). The naïve evaluation algorithm for (positive) Datalog re-disCOVERS each fact from step $t$ again at steps $t + 1, t + 2, \ldots$. The semi-naive algorithm aims at avoiding this, by computing only the new facts. We generalize the semi-naive evaluation from the boolean semiring to any ordered pre-semiring $S$, and prove it correct using the $FGH$-rule. We require $S$ to be a complete distributive lattice and $\oplus$ to be idempotent, and define the “minus” operation as: $b \ominus a \overset{\text{def}}{=} \land \{ c \mid b \leq a \land c \}$, then prove using the $FGH$-rule the following programs equivalent:

\[ \Pi_1 : \quad \Delta_0 := \emptyset; \quad |X| := \emptyset; \quad \Delta_0 := F(\emptyset) \land \emptyset; \quad (\equiv F(\emptyset)) \]

\[ \Pi_2 : \quad \Delta_1 := F(Y_1) \land Y_1; \quad |X| := \emptyset; \quad \Delta_0 := Y_1 \ominus \Delta_1 \quad \ominus \Delta_1 := F(Y_1) \land Y_1; \]

To prove their equivalence, we define $G(X) \overset{\text{def}}{=} (X, F(X) \times X)$, $H(X, \Delta) \overset{\text{def}}{=} (X \ominus \Delta, F(X \ominus \Delta) \otimes (X \ominus \Delta))$, and then we prove that $G(F(X)) = H(G(X))$ by exploiting the fact that $S$ is a complete distributive lattice. In practice, we compute the difference $\Delta_1 = F(Y_1 \ominus Y_1 = F(Y_{1-1} \ominus \Delta_{1-1}) \ominus F(Y_{1-1})$ using an efficient differential rule that computes $\delta F(Y_{1-1} \ominus \Delta_{1-1}) \ominus F(Y_{1-1})$, where $\delta F$ is an incremental update query for $F$, i.e., it satisfies the identity $F(Y) \ominus \delta F(Y, \Delta) = F(Y \ominus \Delta)$. Thus, semi-naive query evaluation generalizes from standard Datalog over the Booleans to Datalog over any complete distributive lattice with idempotent $\oplus$, and, moreover, is a special case of the $FGH$-rule. However, the semi-naive program (more precisely, function $H$) is no longer monotone, while our synthesizer (described in Sec. 6) is currently restricted to infer monotone functions $H$. For
that reason we do not synthesize the semi-naïve algorithm; instead we apply it using pattern-matching as the last optimization step.

3.2 Loop Invariants

More advanced uses of the FGH-rule require a loop-invariant, \( \phi(X) \). By refining Theorem 3.1 with a loop invariant we obtain the following corollary:

**Corollary 3.7.** Let \( \phi(X) \) be any predicate satisfying the following three conditions:

\[
\begin{align*}
\phi(X_0) & \quad (9) \\
\phi(X) & \Rightarrow \phi(F(X)) \quad (10) \\
\phi(X) & \Rightarrow (G(F(X)) = H(G(X))) \quad (11)
\end{align*}
\]

then the FG-program (3) is equivalent to the GH-program (4).

To prove the corollary, we consider the restriction of the function \( F \) to values \( X \) that satisfy \( \phi \). Conditions (9) and (10) state that \( \phi \) is a loop invariant for the FG-program (3), while condition (11) is the FGH-rule applied to the restriction of \( F \) to \( \phi \).

**Example 3.8 (Beyond Magic).** By using loop-invariants, we can perform optimizations that are more powerful than standard magic set rewritings. For a simple illustration, consider the following program:

\[
\Pi_1 : \quad TC(x, y) \rightarrow [x = y] \lor \exists z(E(x, z) \land TC(z, y)) \quad (12)
\]

\[
Q(y) \rightarrow TC(a, y)
\]

which we want to optimize to:

\[
\Pi_2 : \quad Q(y) \rightarrow [y = a] \lor \exists z(Q(z) \land E(z, y)) \quad (13)
\]

Unlike the simple magic program in Example 3.5, here rule (12) is right-recursive. As shown in [6], the magic set optimization using the standard sideways information passing optimization [1] yields a program that is more complicated than our program (13). Indeed, consider a graph that is simply a directed path \( a_0 \rightarrow a_1 \rightarrow \cdots \rightarrow a_n \) with \( a_0 = a_n \). Then, even with magic set optimization, the right-recursive rule (12) needs to derive quadratically many facts of the form \( T(a_i, a_j) \) for \( i \leq j \), whereas the optimized program (13) can be evaluated in linear time. Note also that the FGH-rule cannot be applied directly to prove that the program (12) is equivalent to (13).

To see this, denote by \( P_1 \equiv G(F(TC)) \) and \( P_2 \equiv H(G(TC)) \), and observe that \( P_1, P_2 \) are defined as:

\[
\begin{align*}
P_1(y) & \equiv [y = a] \lor \exists z(E(a, z) \land TC(z, y)) \\
P_2(y) & \equiv [y = a] \lor \exists z(TC(a, z) \land E(z, y))
\end{align*}
\]

In general, \( P_1 \neq P_2 \). The problem is that the FGH-rule requires that \( G(F(TC)) = H(G(TC)) \) for every input \( TC \), not just the transitive closure of \( E \). However, the FGH-rule does hold if we restrict \( TC \) to relations that satisfy the following loop-invariant \( \phi(TC) \):

\[
\exists z_1(E(x, z_1) \land TC(z_1, y)) \Rightarrow \exists z_2(TC(x, z_2) \land E(z_2, y)) \quad (14)
\]

If \( TC \) satisfies this predicate, then it follows immediately that \( P_1 = P_2 \), allowing us to optimize the program (12) to (13). It remains to prove that \( \phi \) is indeed an invariant for the function \( F \). The base case (9) holds because both sides of (14) are empty when \( TC = \emptyset \). It remains to check \( \phi(TC) \Rightarrow \phi(F(TC)) \). Let us denote

\[
\Psi_1(x, y) \equiv \exists z_1(E(x, z_1) \land \{z_2 = y\} \lor \exists z(E(z_1, z) \land TC(z, y))) \quad (15)
\]

\[
\Psi_2(x, y) \equiv \exists z_2(E(x, z_1) \land \{z_2 = y\} \lor \exists z(E(z_1, z) \land TC(z, y))) \quad (16)
\]

\[
TC_0 \equiv F(TC), \quad \text{then we need to check that, if (14) holds, then the predicate } \Psi_1(x, y) \text{ is equivalent to the predicate } \Psi_2(x, y) \text{.}
\]

Example 3.9 (Semantic Optimization). Consider a hierarchy of subparts consisting of two relations: \( \text{SubPart}(x, y) \) indicates that \( y \) is a subpart of \( x \), and \( \text{Cost}(x) \in \mathbb{N} \) represents the cost of the part \( x \). We want to compute, for each \( x \), the total cost \( Q[x] \) of all its subparts, sub-subparts, etc. Since the hierarchy can be a DAG, we first need to compute the transitive closure, before summing up the costs of all subparts, sub-subparts, etc:

\[
\Pi_1 : \quad S(x, y) \rightarrow [x = y] \lor \exists z(S(x, z) \land \text{SubPart}(z, y)) \quad (15)
\]

\[
Q(x) \rightarrow \sum_y \{\text{Cost}(y) \mid S(x, y)\} \quad (16)
\]

The first rule, defining the \( S \) predicate, is over the \( \mathbb{B} \) semiring, while the second rule, defining \( Q \), is over the \( \mathbb{N} \) semiring. Consider now the case when our subpart hierarchy is a tree. Then, we can compute the total cost much more efficiently, using the following program:
The first asserts that \( P \) and by \( F, G \), transitively closed, and irreflexive. Next, we infer the following program, denote by \( X \) one stratum at a time. We denote by \( \Pi \) discussed in Sec. 7. Next, the optimizer needs to find \( \Gamma \), whose architecture is shown in Fig. 6. We optimize \( P \) as line 5 of Fig. 5, proving that \( \Pi = G(F(S)) \) is equivalent to \( \Pi = H(G(S)) \), since this only holds if the database instance is a tree. Inference that there exists some relation \( T \) on line 3 is equivalent to \( \Pi \), and the database constraint \( \Gamma \). The output consists of the optimized program \( \Pi_2 \), see Eq. (6). Blue boxes are described in Section 6 and the green boxes in Section 7. The yellow box (generalized semi-naive optimization) is described in Section 3.1. The red boxes represent three state-of-the-art systems: Rosette is a CEGIS system [43, 45, 46], z3 is an SMT solver [9], and EGG is an ETSAT system[53].

\[
P_1[x] = \sum_y \{\text{Cost}[y] \mid [x = y] \lor \exists z (S(x, z) \wedge \text{SubPart}(z, y))\}
\]

\[
= \text{Cost}[x] + \sum_y \{\text{Cost}[y] \mid [x = y] \land \exists z (S(x, z) \wedge \text{SubPart}(z, y))\}
\]

\[
- \sum_y \{\text{Cost}[y] \mid [x = y] \land \exists z (S(x, z) \wedge \text{SubPart}(z, y))\}
\]

\[
= \text{Cost}[x] + \sum_y \{\text{Cost}[y] \mid [x = y] \land \exists z (S(x, z) \wedge \text{SubPart}(z, y))\}
\]

\[
= \text{Cost}[x] + \sum_y \sum_z \{\text{Cost}[y] \mid (S(x, z) \wedge \text{SubPart}(z, y))\}
\]

Figure 5: Transformation of \( P_1 = G(F(S)) \) in Example 3.9.

Optimizing the program (15) to (16) is an instance of semantic optimization, since this only holds if the database instance is a tree. We do this in three steps. We define the constraint \( \Gamma \) stating that the data is a tree; using \( \Gamma \) we infer a loop-invariant \( \Phi \) of the program \( \Pi_1 \); using \( \Gamma \) and \( \Phi \) we prove the FGH-rule, concluding that \( \Pi_1 \) is equivalent to \( \Pi_2 \).

The constraint \( \Gamma \) is the conjunction of the following statements:
\[
\forall x_1, x_2, y (\text{SubPart}(x_1, y) \wedge \text{SubPart}(x_2, y) \Rightarrow x_1 = x_2) \quad (17)
\]
\[
\forall x, y (\text{SubPart}(x, y) \Rightarrow T(x, y)) \quad (18)
\]
\[
\forall x, y, z (T(x, z) \wedge \text{SubPart}(z, y) \Rightarrow T(x, y)) \quad (19)
\]
\[
\forall x, y (T(x, y) \Rightarrow x \neq y) \quad (20)
\]

The first asserts that \( y \) is a key in \( \text{SubPart}(x, y) \). The last three are an Existential Second Order Logic (ESO) statement: they assert that there exists some relation \( T(x, y) \) that contains \( \text{SubPart}(x, y) \), is transitively closed, and irreflexive. Next, we infer the following loop-invariant of the program \( \Pi_1 \):
\[
\Phi : S(x, y) \Rightarrow [x = y] \lor T(x, y) \quad (21)
\]

Finally, we check the FGH-rule, under the assumptions \( \Gamma, \Phi \). Denote by \( P_1 \equiv G(F(S)) \) and \( P_2 \equiv H(G(S)) \). To prove \( P_1 = P_2 \) we simplify \( P_1 \) using the assumptions \( \Gamma, \Phi \), as shown in Fig. 5. We explain each step. Line 2-3 are inclusion/exclusion. Line 4 uses the fact that the term on line 3 is \( 0 \), because the loop invariant implies:
\[
S(x, z) \land \text{SubPart}(z, y) \Rightarrow ([x = z] \lor T(x, z)) \land \text{SubPart}(z, y) \quad (21)
\]
\[
\equiv \text{SubPart}(x, y) \lor (T(x, z) \land \text{SubPart}(z, y)) \quad (21)
\]
\[
\equiv [x = y] \lor T(x, y) \quad (19)
\]
\[
\equiv T(x, y) \quad (19)
\]
\[
\equiv x \neq y \quad (20)
\]

Line 5 follows from the fact that \( y \) is a key in \( \text{SubPart}(z, y) \). A direct calculation of \( P_2 = H(G(S)) \) results in the same expression as line 5 of Fig. 5, proving that \( P_1 = P_2 \).

4 ARCHITECTURE OF FGH-OPTIMIZATION

In the rest of the paper we describe our synthesis-based FGH-optimizer, whose architecture is shown in Fig. 6. We optimize one stratum at a time. We denote by \( \Pi_0 \) one stratum of the input program, denote by \( X \) its recursive IDBs, by \( Y \) its output IDBs, and by \( F, G \) the ICO and the output operator respectively; see Eq. (6). The optimizer also takes as input a database constraint, \( \Gamma \). The optimizer starts by inferring the loop invariant \( \Phi \); this is discussed in Sec. 7. Next, the optimizer needs to find \( H \) such that

\[
\Gamma \land \Phi \models (G(F(S)) = H(G(S))).
\]

To reduce clutter we will often abbreviate this to \( \Gamma \models (G(F(S)) = H(G(S))) \), assuming that \( \Gamma \) incorporates \( \Phi \). The optimizer makes two attempts at synthesizing \( H \): it first tries using a simpler rule-based synthesizer, and, if that fails, then it tries the state-of-the-art Counterexample-Guided Inductive Synthesis (CEGIS). This is described in Sec. 6. Finally, \( H \) (or the original program if the FGH-optimization failed) is further transformed using generalized semi-naive optimization, as we already described in Sec. 3.1. Notice that stratification ensures that no interpreted functions are applied to the IDBs \( X \); they can still be applied to the EDBs, or occur in predicates.

The FGH-optimization is an instance of query rewriting using views [16, 21]. Denoting by \( Q \defeq G(F(S)) \) and \( V \defeq G(X) \), one has to rewrite the query \( Q \) using the \( V \)-views, in other words \( Q = H(V) \). This is a total rewriting, in the sense that \( H \) may no longer refer to the IDBs \( X \). This problem is NP-complete for UCQs with set semantics [26], in NP for UCQs with bag semantics [5], and undecidable for realistic SQL queries that include aggregates and arithmetic [16]. Systems that support query rewriting using views are rule-based, and apply a set of hand crafted, predefined patterns; our first attempt to synthesize \( H \) is also rule-based. Such synthesizers usually cannot take advantage of database constraints, but we will show in Sec. 7 how to exploit the constraint \( \Gamma \) in the rule-based synthesizer. However, rule-based rewriting explores a limited space, which is insufficient for many FGH-optimizations. In a seminal paper [43] Solar-Lezama proposed an alternative to rule-based transformation, called Counterexample-Guided Inductive Synthesis (CEGIS): the synthesizer produces potentially incorrect candidates,

\[\text{This follows from the fact that, under bag semantics, two UCQ queries are equivalent if they are isomorphic. [17, 52].}\]
and an SMT solver verifies their correctness. In the FGH-optimizer we use a program synthesizer, Rosette [45], to synthesize H.

At a conceptual level, program synthesis has two abstract steps: generate H, and verify G(F(X)) = H(G(X)). While the verifier is not used explicitly, it is used implicitly in the synthesizer, and we describe it in Sec. 5. Then we describe the synthesizer in Sec. 6.

5 VERIFICATION

We introduced the FGH-rule in Sec. 3 and showed several examples. In order to apply the rule, one needs to check the identity (5), $F(G(X)) = G(H(X))$. In this section we describe how we verify this identity. This step is implicit in both boxes Rule-based Synthesis and CEGIS in Fig 6. The identity can be checked in one of two ways: by applying a predefined set of identity rules (as currently done by most query optimizers), or by using an SMT solver.

5.1 Rule-based Test

Let $P_1 = G(F(X))$, $P_2 = H(G(X))$. To check $P_1 = P_2$, the rule-based test first normalizes both expressions into a sum-sum-product expression (Eq. (2)) via the semiring axioms, then checks if the expressions are isomorphic: if yes, then $P_1 = P_2$, otherwise we assume $P_1 \neq P_2$. The treatment of a constraint $\Gamma$ will be discussed in Sec. 7. This test can be visualized as follows:

$$P_1 \xrightarrow{\text{axioms}} \text{normalize}(P_1) \approx \text{normalize}(P_2) \xrightarrow{\text{axioms}} P_2 \quad (22)$$

where $\approx$ denotes isomorphism. The Rule-based test is sound. When both $P_1, P_2$ are over the $\mathbb{N}^\omega$ semiring and have no interpreted functions then it is also complete [17, 52]. This simple test motivates the need for a complete set of axioms that allows any semiring expression to be normalized. The axioms include standard semiring axioms, and axioms about summations and free variables $fv$. For example, in order to prove $CC_1 = CC_2$ in Example 3.3 (with semiring notation in Figure 7) one needs all three axioms below:

$$\bigoplus_y \bigotimes_y (\ldots) = \bigoplus_y (\ldots) \quad (23)$$

$$A \otimes \bigoplus_x B = \bigoplus_x A \otimes B \text{ when } x \not\in fv(A) \quad (24)$$

$$\bigotimes_x (A(x) \otimes [x = y]) = A(y) \quad (25)$$

5.2 SMT Test

When the expressions $P_1, P_2$ are over a semiring other than $\mathbb{N}^\omega$, or they contain interpreted functions, then the rule-based test is insufficient and we use an SMT solver for our verifier. We still normalize the expressions using our axioms, because today’s solvers cannot reason about bound/free variables (as needed in axioms (23)-(25)). The SMT test is captured by the following figure:

$$P_1 \xrightarrow{\text{axioms}} \text{normalize}(P_1) \xrightarrow{\text{SMT}} \text{normalize}(P_2) \xleftarrow{\text{axioms}} P_2 \quad (26)$$

Example 5.1 (APSP100). Consider a labeled graph $E$ where $E[x, y]$ represents the cost of the edge $x, y$. The following query over $\text{Trop}$ computes the all-pairs shortest path up to length of 100:

$$Q[x, y] : = \min(D[x, z] + E[z, y])$$

In this particular semiring, the program is inefficient because it first computes the full path length, only to cap it later to 100. By using the FGH-rule we get:

$$Q(x, y) : = \min(D[0, x], 100) \quad (27)$$

The program is inefficient because it first computes the full path length, only to cap it later to 100. By using the FGH-rule we get:

$$Q(x, y) : = \min(D[0, x], 100) \quad (28)$$

We show how to verify that (28) is equivalent to (27). Denote by $P_1 \overset{\text{def}}{=} G(F(D))$ and $P_2 \overset{\text{def}}{=} H(G(D))$ (where $F, G, H$ are the obvious functions in the two programs defining $Q$). After we de-sugar, convert to semiring expressions, and normalize, they become:

$$P_1[x, y] = (0 \oplus [x = y] \ominus \bigoplus_x D[x, z] \ominus E[z, y]) \ominus 100 \quad (29)$$

$$P_2[x, y] = (0 \oplus [x = y] \ominus \bigoplus_x D[x, z] \ominus E[z, y]) \ominus (100 \ominus \bigoplus_z E[z, y]) \ominus 100 \quad (30)$$

In the normalized expressions we push the summations past the joins, i.e., we apply rule (24) from right to left, thus we write $100 \ominus \bigoplus_z (\cdots)$ instead of $(\bigoplus_z 100 \ominus \cdots)$: we give the rationale below. At this point, the normalized $P_1$ and $P_2$ are not isomorphic, yet they are equivalent if they are interpreted in $\text{Trop}$. We explain below in detail how the solver can check that. In this particular semiring, the identity $100 = (100 \ominus \bigoplus_z E[z, y]) \ominus 100$ holds since it becomes $100 = \min(100+\min_z E[z, y], 100)$ with $E[z, y] \geq 0$, once we replace the uninterpreted operators $\ominus, \ominus$ with $\min, \ast$.

Implementation

We describe how we implemented the SMT test $\Gamma \models P_1 = P_2$ using a solver, now also taking the database constraint $\Gamma$ into account, where $P_1, P_2$ are the expressions $G \circ F$ and $H \circ G$. We used the z3 solver [9], but our discussion applies to other solvers as well. We need to normalize $P_1, P_2$ before using the solver, because solvers require all axioms to be expressed in First Order Logic. They cannot encode the axioms (23)-(25), because they are referring to free variables, which is a meta-logical condition not expressible in First Order Logic. Once normalized, we encode the equality as a first-order logic formula, and assert its negation, asking the solver to check if $\Gamma \land (P_1 \neq P_2)$ is satisfiable. The solver returns UNSAT, a counterexample, or UNKNOWN. UNSAT means the identity holds. When it returns a counterexample, then the identity fails, and the counterexample is given as input to the synthesizer (Sec. 6). UNKNOWN means that it could neither prove nor disprove the equivalence and we assume $P_1 \neq P_2$. For the theory of reals with $+, \ast$, despite its decidability, z3 often timed out in our experiments. We therefore used the theory of integers, and z3 never timed out or returned UNKNOWN in our experiments.

We encode every $S$-relation $R(x_1, \ldots, x_n)$ as an uninterpreted function $R : \mathbb{N} \times \cdots \times \mathbb{N} \to S$, where $S$ is the interpreted semiring, i.e., $\mathbb{B}$, $\text{Trop}$, $\mathbb{N}^\omega$, etc. We represent natural numbers as integers with nonnegativity assertions, and represent the sets $\mathbb{N}^\omega, \mathbb{N}, \mathbb{R}, \mathbb{R}$ as union types. Operators supported by the solver, like $+, \ast, \min, \ast$, are entered unchanged; we treat other operators as uninterpreted.
functions. Unbounded aggregation, like $\bigoplus \varepsilon(x)$, poses a challenge: there is no such operation in any SMT theory. Here we use the fact that $P_1$ and $P_2$ are normalized sum-sum-product expressions:

$$P_1 = \bigoplus_{x_1} e_1 \oplus \bigoplus_{x_2} e_2 \cdots \quad P_2 = \bigoplus_{x'_1} e'_1 \oplus \bigoplus_{x'_2} e'_2 \cdots$$

Assume first that each $x_i$ is a single variable. We ensure that all the variables $x_1, x_2, \ldots$ in $P_1$ are distinct, by renaming them if necessary. Next, we replace each expression $\bigoplus_{x_i} e_i$ with $u(x_i, e_i)$ where $u$ is an uninterpreted function. Therefore, the identity $u(x, e) = u(x', e')$ holds iff $x = x'$ and $e = e'$. We ask the solver to check

$$\Gamma \models \left( u(x_1, e_1) \oplus u(x_2, e_2) \cdots = u(x'_1, e'_1) \oplus u(x'_2, e'_2) \cdots \right)$$

This procedure is sound, because if the identity $u(x, e) = u(x', e')$ holds, then $x = x'$ (they are the same variable) and $e = e'$, which means that $\bigoplus_x e = \bigoplus_x e'$. Moreover, when synthesizing $P_2$, we will ensure that the generator includes the variables $x_1, x_2, \ldots$ present in $P_1$ to achieve a limited form of completeness, see Sec. 6. Finally, if a summation is over multiple variables, we simply nest the uninterpreted function, i.e., write $\bigoplus_{x, y} e$ as $u(x, u(y, e))$.

**Example 5.2.** We now finish Example 5.1. After introducing the uninterpreted functions described above, we obtain:

$$P_1 = \min(0 + w(x, y), u(z, D[x, z] + E[z, y]), 100)$$

$$P_2 = \min(0 + w(x, y), u(z, D[x, z] + E[z, y]), 100 + u(z, E[z, y]), 100)$$

where $w(x, y)$ is an uninterpreted function representing $|x - y|^6$, and $u$ is our uninterpreted function encoding summation. The solver proves that the two expressions are equal, given that $w \geq 0$ and $u \geq 0$. Notice that it was critical to factorize the term 100: had we not done that, then the expression $100 + u(z, E[z, y])$ would be $u(z, 100 + E[z, y])$ and the identity $P_1 = P_2$ no longer holds.

**Discussion** Readers unfamiliar with First Order Logic may be puzzled by our statement that the identity $u(x, e) = u(x', e')$ holds iff $x = x'$ and $e = e'$. In order to explain this, it helps to first review the basic definitions of validity and satisfiability in logic. A statement is “valid” if it is true for all interpretations of its uninterpreted symbols. For example, the equality $f(x) + y = y + f(x)$ is valid over integers, because it holds for all functions $f$ and all values of $x$ and $y$. A statement is “satisfiable” if there exists interpretations of its uninterpreted symbols that make the statement true. A statement is valid if its negation is not satisfiable. In our case, the statement $u(x, e) = u(x', e')$ is valid if the equality is true for all possible interpretations of $u, x, x'$. For example, suppose we asked the solver to check whether $u(x, 2(x + 1)) = u(y, 2y + 2)$ is valid. To answer this question, we negate the statement and ask the $z$ solver whether the negation is satisfiable: $u(x, 2(x + 1)) \neq u(y, 2y + 2)$. One can easily satisfy this with pen and paper, e.g., $x = 1, y = 2, u(a, b) = a + b$, then $u(x, 2(x + 1)) = 5, u(y, 2y + 2) = 8$. $z$ also answers “yes”, and provides the following example for the inequality:

$$x = 0, y = 38, u(a, b) = a = 38 \land b = 78 \text{ then } 6 \text{ else } 4$$

Therefore, the identity $u(x, 2(x + 1)) = u(y, 2y + 2)$ is not valid. In contrast, suppose we asked the solver whether $u(x, 2(x + 1)) = u(x, 2x + 2)$ is valid. Its negation is $u(x, 2(x + 1)) \neq u(x, 2x + 2)$.

6 \ SYNTHESIS

We have seen in Sec. 5 how to use an SMT solver to check the identity $G(F(X)) = H(G(X))$. We are now ready to discuss the core of the FGH-optimizer: given the query expressions $F, G$, find $H$ such that the identity $G(F(X)) = H(G(X))$ holds; recall that we denote these expressions by $P_1, P_2$. As for verification, this can be done by using only rewriting, or using program synthesis with an SMT solver. We are also given a database constraint $\Gamma$, and we assume that we have already added to it the loop invariant $\Phi$.

6.1 \ Rule-based Synthesis

The optimizer first attempts to synthesize $H$ using rule-based rewriting. This process is akin to our initial verifier that relies only on normalization and isomorphism checking.

$$P_1 \xrightarrow{\text{axioms}} \text{normalize}(P_1) \xrightarrow{\text{CEGIS}} P_2 \quad (29)$$

There is no obvious way to “denormalize” an expression, since many expressions share the same normal form. We used for this purpose an equality saturation system (EQSAT), also used for multiple tasks of the FGH-optimizer, see Fig 6. We describe EQSAT in Sec. 7.

6.2 \ Counterexample-based Synthesis

The rule-based synthesis (29) explores only correct rewritings $P_2$, but its space is limited by the hand-written axioms. The alternative approach, pioneered in the programming language community [43], is to synthesize candidate programs $P_2$ from a much larger space, then using an SMT solver to verify their correctness. This technique, called Counterexample-Guided Inductive Synthesis, or CEGIS, can find rewritings $P_2$ even in the presence of interpreted functions, because it exploits the theory of the underlying domain. As a first attempt it can be described as follows (we will revise it below):

$$P_1 \xrightarrow{\text{axioms}} \text{normalize}(P_1) \xrightarrow{\text{CEGIS}} P_2 \quad (30)$$

6.2.1 \ Brief Overview of CEGIS

We give a brief overview of the CEGIS system, Rosette [45, 46], that we used in our optimizer. Understanding its working is important in order to optimize its usage for FGH-optimization. The input to Rosette consists of a specification and a grammar, and the goal is to synthesize a program defined by the grammar and that satisfies the specification. The main loop is implemented with a pair of dueling SMT-solvers, the generator and the checker. In our setting, the inputs are the query $P_1$, the database constraint $\Gamma$, and a small grammar $\Sigma$ (described below).

The specification is $\Gamma \models (P_1 = P_2)$, where $P_2$ is defined by the grammar $\Sigma$. The generator generates syntactically correct programs $P_2$, and the verifier checks $\Gamma \models (P_1 = P_2)$. In the most naive attempt, the generator could blindly generate candidates $P_2, P_2', P_2'', \ldots$, until one is found that the verifier accepts. This is hopelessly inefficient. The first optimization in CEGIS is that the verifier returns a small counterexample database instance $D$ for each unsuccessful candidate $P_2$, i.e., $P_1(D) \neq P_2(D)$. When considering a new candidate $P_2$, the generator checks that $P_1(D_1) = P_2(D_1)$ holds for all previous counterexamples $D_1, D_2, \ldots$, by simply evaluating the queries $P_1, P_2$.
on the small instance $D_1$. This significantly reduces the search space of the generator.

CEGIS applies a second optimization, where it uses the SMT solver itself to generate the next candidate $P_2$, as follows. It requires a fixed recursion depth for the grammar $\Sigma$; in other words we can assume w.l.o.g. that $\Sigma$ is non-recursive. Then it associates a symbolic Boolean variable $b_1, b_2, \ldots$ to each choice of the grammar. The grammar $\Sigma$ can be viewed now as a BDD (binary decision diagram) where each node is labeled by a choice variable $b_j$, and each leaf is a recursively specified program $P_2$. The search space of the generator is now completely defined by the choice variables $b_j$, and Rosette uses the SMT solver to generate values for these Boolean variables such that the corresponding program $P_2$ satisfies $P_1(D_1) = P_2(D_1)$, for all counterexample instances $D_1$. This significantly speeds up the choice of the next candidate $P_2$.

6.2.2 Using Rosette. To use Rosette, we need to define the specification and the grammar. A first attempt is to simply define some grammar for $H$, with the specification $\Gamma \models G(F(G)) = H(G(X))$. This does not work, since Rosette uses the SMT solver to check the identity: as explained in Sec. 5.2, modern SMT solvers have limitations that require us to first normalize $G(F(G))$ and $H(G(X))$ before checking their equivalence. Even if we modify Rosette to normalize $H(G(X))$ during verification, there is still no obvious way to incorporate normalization into the program generator driven by the SMT solver. Instead, we define a grammar $\Sigma$ for $\text{normalize}(H(G(X)))$ rather than for $H$, and then specify:

$$\Gamma \models \text{normalize}(G(F(G))) = \text{normalize}(H(G(X)))$$

Then, we denormalize the result returned by Rosette, in order to extract $H$, using the denormalization module in Fig. 6, described in Sec. 7. In summary, our CEGIS-approach for FGH-optimization can be visualized as follows:

$$P_1 \xrightarrow{\text{axioms}} \text{normalize}(P_1) \xrightarrow{\text{CEGIS}} \text{normalize}(P_2) \xrightarrow{\text{axioms}} P_2 \quad (31)$$

The choice of the grammar $\Sigma$ is critical for the FGH-optimizer. If it is too restricted, then the optimizer will be limited too, if it is too general, then the optimizer will take a prohibitive amount of time to explore the entire space. We briefly describe our design at a high level. Recall that $X$ denotes multiple IDBs, and the query $G(X)$ may also return multiple intermediate relations. In our system $G(X)$ is restricted to return a single relation, so we will assume that $Y = G(X)$ is a single IBD. The expression $G$ is known to us, and is a sum-of-product expression, see Eq. (2).

$$G(X) = G_1(X) \cdot \cdots \cdot G_m(X)$$

where each $G_i(X)$ is a sum-product expression, Eq. (1), using the IDBs $X$ and/or the EDBs.

To generate $\text{normalize}(H(G(X)))$, we group their sum-products by the number of occurrences of $Y$:

$$\text{normalize}(H(Y)) = H^{(0)}(Y) \oplus \cdots \oplus H^{(k_{\max})}(Y)$$

where $H^{(k)}$ is a sum-product $H^{(k)} = Q_1 \cdot Q_2 \cdot \cdots$ s.t. each $Q_i$ contains exactly $k$ occurrences of $Y$, and an arbitrary number of EDBs (it may not contain the IDBs $X$). We choose $k_{\max}$ as the largest number of recursive IDBs $X$ that occur in any rule of the original program $P(X)$, e.g., if the original program was linear, then

\begin{align*}
A &\rightarrow A_0 \oplus A_1 \oplus \cdots \oplus A_{k_{\max}}^A, \\
A_0 &\rightarrow Q_0 \mid Q_0 \oplus \cdots \mid E(Z, Z, \ldots, Z), \\
A_1 &\rightarrow A_1 \oplus \cdots \oplus A_{1m}, \\
A_2 &\rightarrow A_2 \oplus \cdots \oplus A_{2m}, \\
A_3 &\rightarrow A_{311} \oplus \cdots \\
A_{ij} &\rightarrow Q_{ij} \oplus A_{ij}, \\
A_{ij} &\rightarrow Q_{ij} \oplus u(Z, Q_{ij}), \\
A_{ij} &\rightarrow A_{ij} \oplus (Q_{ij} \oplus G_i(X)), \quad i = 1, m \\
A_{ij} &\rightarrow A_{ij} \oplus (Q_{ij} \oplus G_i(X)), \quad j = 1, m \\
A_{ij} &\rightarrow A_{ij} \oplus A_{ij} \rightarrow A_{ij} \oplus (Q_{ij} \oplus Q_{ij}), \quad i, j, k = 1, m
\end{align*}

Figure 8: Grammar $\Sigma$ for $\text{normalize}(H(G(X)))$, for $k_{\max} = 3$.

Figure 9: Example e-graph.

The grammar $\Sigma$ is shown in Fig. 8. The start symbol, $A$, generates a sum matching the expression above. $A_0$ generates $H^{(0)}$, which is a sum of sum-product terms without any occurrence of $Y$. Recall from Sec. 5.2 that the expression $u(z, Q)$ denotes $\bigoplus_z Q$. $E$ is one of the EDBs, and $Z$ is a non-terminal for which we define rules $Z \rightarrow z_1 | z_2 | \cdots | z_m | z_1 | z_2 | \cdots$ where $z_1, \ldots, z_m$ are variables that already occur in $G(F(G(X)))$, and $z_1, z_2, \ldots$ is some fixed set of fresh variable names. $A_0$ generates $\text{normalize}(H^{(0)}(G(X)))$, which is a sum of sum-products, each with exactly $k$ occurrence of $Y$. As stated in Fig. 8, the rules for $A_0$ are incorrect. For example consider $A_3$: the $m$ non-terminals $A_{11}, \ldots, A_{1m}$ should have identical derivations, instead of being expanded independently. For example, assume $G = G_1 \oplus G_2$ (thus $m = 2$) and we want $H$ to be one of $E_1 \oplus Y$ or $E_2 \oplus Y$ or $E_3 \oplus Y$. Then, $\text{normalize}(H(G(X)))$ can be one of the following three expressions $E_1 \oplus G_1 \oplus G_2$ or $E_2 \oplus G_1 \oplus E_2 \oplus G_2$ or $E_3 \oplus G_1 \oplus E_3 \oplus G_2$. However, the grammar $A_3 \rightarrow A_{11} \oplus A_{12}$ also generates incorrect expressions $E_1 \oplus G_1 \oplus E_2 \oplus G_2$, because $A_{11}, A_{12}$ can choose independently the IBD $E_1, E_2$, or $E_3$. We fix this by exploiting the choice variables in Rosette: we simply use the same variables in $A_{11}, A_{12} \ldots$ ensuring that all these non-terminals make exactly the same choices. We note that our current system is restricted to linear programs, hence $k_{\max} = 1$.

6.2.3 Discussion. Even though our grammar is restricted to $k_{\max} = 1$, it is more complex than Fig 8, in order to further reduce the search space. We use more non-terminals to better control which variables $z$ can be used, and we also consider the choice of including entire subexpressions that occur in the original program $P_1$, since they are often reused in the optimized program. The synthesizer would require many trials to find them, had we not included them explicitly.
We implemented a source-to-source FGH-optimizer, based on Fig. 6. Throughout the FGH-optimizer we need to manipulate expressions, together with an equivalence relation over this set. Each e-graph consists of a set of e-classes, each e-class consists of a set of e-nodes, and each e-node is a function symbol with e-classes as children. Figure 9 shows an e-graph representing the two expressions in Eq. (24), their subexpressions, and other equivalent expressions. Each e-class (dotted box) represents a class of equivalent expressions. For example e-class 5 represents \( A \otimes B \) and \( B \otimes A \), which are equivalent by commutativity. e-class 6 represents four equivalent expressions (including the two choices in e-class 5).

The EQSAT system maintains separately a collection of rules, each represented by a pair of patterns. For example, one rule may state that \( \otimes \) is commutative: \( x \otimes y = y \otimes x \). The e-graph can efficiently add a new expression to its collection, insert a new rule, and match a given expression against the e-graph.

We describe how we use EGG in the FGH-optimizer. First, we use it to extend the Rule-based test (Sec. 5.1) to account for a constraint \( \Gamma \). By design, the e-graph makes it easy to infer the equivalence \( P_1 = P_2 \) from a set of rules. Suppose we want to check such an equivalence conditioned on \( \Gamma \). We may assume w.l.o.g. that \( \Gamma \) is a logical implication, \( \Delta \Rightarrow \Theta \) since all database constraints are expressed this way. We convert it into an equivalence \( \Delta \land \Theta = \Delta \), and insert it into the e-graph, then check for equivalence \( P_1 = P_2 \).

Second, we use the e-graph to denormalize an expression. More precisely, recall from Sec. 6.1 that we attempt to synthesize \( H \) by denormalizing \( P_1 = \text{normalize}(F(G(X))) \), in other words, writing it in the form \( H(G(X)) \). For that we add \( G(X) \) to the e-graph, observe in which e-class it is inserted, and replace that e-class with a new node \( Y \). The root of the new e-graph represents many equivalent expressions, and each of them is a candidate for \( H \). We choose the expression \( H \) that has the smallest AST and does not have any occurrence of the IDBs \( X \).

Finally, we use the e-graph to infer the loop invariants. We do this by symbolically executing the recursive program \( P \) for up to 5 iterations, and compute the symbolic expressions of the IDBs \( X, X_0, X_1, \ldots \). Using an e-graph we represent all identities satisfied by these (distinct!) expressions. The identities that are satisfied by every \( X_i \) are candidate loop invariants: for each of them we use the SMT solver to check if they satisfy Eq. (10) from Sec. 3.2.

## 8 Evaluation

We implemented a source-to-source FGH-optimizer, based on Fig. 6. The input is a program \( P_1 \), given by \( F, G \), and a database constraint \( \Gamma \), and the output is an optimized program \( H \). We evaluated it on three Datalog systems, and several programs from benchmarks proposed by prior research [12, 38]; we also propose new benchmarks that perform standard data analysis tasks. We did not modify any of the three Datalog engines. We asked two major questions:

1. How effective is our source-to-source optimization, given that each system already supports a range of optimizations?
2. How much time does the actual FGH optimization take?

### 8.1 Setup

There is a great number of commercial and open-source Datalog engines in the wild, but only a few support aggregates in recursion. We were able to identify five major systems with such support: SocialLite [37], Myria [49], the DeALS family of systems [DeALS [40], BigDatalog [39], and RaDlog [20]), RecStep [12], and Dyna [14]. Prior work [38] reports SocialLite and Myria are consistently slower than newer systems, so we do not include them in our experiments. Dyna is designed to experiment with novel language semantics and not for data analytics, and we were not able to run our benchmarks without errors using it. Systems in the DeALS family are similar to each other; we pick BigDatalog because it is open source and runs our benchmarks without errors; we include RecStep for the same reasons. Both BigDatalog and RecStep are multi-core systems. Finally, we run experiments on an unreleased commercial system \( X \), which is single core. As we shall discuss, \( X \) is the only one that supports all features for our benchmarks.

We conducted all experiments on a server running CentOS 8.3.2011. The server has a total of 1008GB memory, and 4 Intel Xeon CPU E7-4890 v2 2.80GHz CPUs, each with 15 cores and 30 threads. We ran seven benchmarks, shown in Fig. 10. BM and CC are Examples 3.8 and 3.3; MLM is basically Example 3.9. CC, SSSP and MLM are from [38], the others are designed by us. R and MLM require a database constraint stating that the data is a tree. BM, R, and MLM each have a non-trivial loop invariant that is inferred by the optimizer. Our optimizer requires each program to consist of two rules, one each for \( F \) and \( G \), and so a meaningful metric for program size is the number of semiring operations. These numbers are listed in the last column of Fig 10. Our benchmark programs are comparable in size to those used in prior work [12, 38]. All programs are available in our git repository. The real-world datasets twitter [27], epinions [33], and wiki [24] are from the popular SNAP collection [25]. We follow the setting in [12, 38] when generating the synthetic graphs. We additionally generate random recursive trees with an exponential decay, modeling the decay of association in multi-level marketing [11]. For WS, we input the vector \([1, \ldots, n]\), since the values of the entries do not affect run time. In general, we used smaller datasets than [12, 38] because some of our experiments run single-threaded.

### 8.2 Run Time Measurement

For each program-dataset pair, we measure the run times of three programs: original, with the FGH-optimization, and with the FGH-optimization and the generalized semi-naive (GSN, for short) transformation. We report only the speedups relative to the original program in Fig. 11 and 12. In some cases the original program timed out our preset limit of 3 hours, where we report the speedup against the 3 hours mark. In some other cases the original program ran out of memory and we mark them with “o.m.” in the figure. The absolute runtimes are irrelevant for our discussion, since we want to report the effect of adding our optimizations. (We also do not have permission to report the runtimes of \( X \).) All three systems...

Figure 13: Optimization time in seconds, optimization time over execution time, and size of the search space.
already perform semi-naive evaluation on the original program, since that is expressed over the Boolean semiring.

The FGH-optimized program is over a different semiring (except for BM), and GSN has non-stratifiable rules with negation, which are supported only by system X; we report GSN only for system X. While the benchmarks in Fig. 11 were on real datasets, those in Fig. 12 use synthetic data, for multiple reasons: we did not have access to a good tree dataset needed in the R and MLM benchmarks, BC timed out on our real data (BC is computationally expensive), and WS uses only a simple array. A benefit of synthetic data is that we can report how the optimizations scale with the data size. Unfortunately, the FGH-optimized programs in Fig. 12 require recursion with SUM aggregation, which is not supported by BigDatalog or RecStep; this is in contrast with those in Fig. 11, which require recursion with MIN aggregation which is supported by all systems.

8.2.1 Findings. Figure 11 shows the results of the first group of benchmarks optimized by the rule-based synthesizer. Overall, we observe our optimizer provides consistent and significant (up to 4 orders of magnitude) speedup across systems and datasets. Only a few datapoints indicate the optimization has little effect: BM and CC on wiki under BigDatalog, and SSPP on wiki under X. This is due to the small size of the wiki dataset: both the optimized and unoptimized programs finish very quickly, so the runtime is dominated by system overhead which cannot be optimized away. We also note that (under X) GSN speeds up SSPP but slows down CC (note the log scale). The latter occurs because the \( \Delta \)-relations for CC are very large, and as a result the semi-naive evaluation has the same complexity as the naive evaluation; but the semi-naive program is more complex and incurs a constant slowdown. GSN has no effect on BM because the program is in the boolean semiring, and X already implements the standard semi-naive evaluation. Optimizing BM with FGH on BigDatalog sees a significant speedup even though the systems already implements magic set rewrite, because the optimization depends on a loop invariant.\(^7\) Overall, both the semi-naive and naive versions of the optimized program are significantly faster than the unoptimized program.

Figure 12 shows the results of the second group of benchmarks, which required CEGIS. Since we used synthetic data, we examined here the asymptotic behavior of the optimization as a function of the data size. The most advanced optimization was for BC, which leads essentially to Brandes’ algorithm [7]; its effect is dramatic. R and MLM rely on semantic optimization for a tree. We generated two synthetic trees, a random recursive tree with expected depth of \( O(\log n) \) and one with exponential decay with expected depth of \( O(n) \). Since the benefit of the optimization depends on the depth, we see a much better asymptotic behavior in the second case. Here, too, the optimizations were always improving the runtime.

8.3 Optimization Time and Search Space

CEGIS can quickly become very expensive if its search space is large, and, for that reason, we have designed the grammar generator carefully to reduce the search space without losing generality. Fig. 13 reports the runtime of the synthesizer (in seconds) for both rule-based synthesis and CEGIS, and the size of the search space.

\(^7\)BigDatalog can optimize the left-recursive version of BM (7) to obtain similar speedup, via the classic magic set rewrite.

The rule-based synthesizer runs in milliseconds, while CEGIS took over 1s for BC (our hardest benchmark). These numbers are close to those demanded by modern query optimizers, and represent only a tiny portion of the total runtime of the optimized query. Optimization time takes less than 1% of the query run time for all benchmarks except for BC and WS on the smallest input data. To our surprise, our grammar managed to narrow the search space considerably, to no more than 132 candidates, which (in hindsight) explains the low optimization times. The search space can grow rapidly, and even exponentially, as the size of the input program grows. Our optimizer optimizes a single stratum at a time, focusing on improving critical “basic blocks” of a program. Our benchmark programs demonstrate a wide range of data analysis computation can be expressed succinctly using just a few semiring operations, and optimization can have a dramatic impact on performance.

8.4 Summary

We conclude that our optimizer can significantly speedup already optimized Datalog systems, either single-core or multi-core. GSN can, sometimes, further improve the runtime. We achieved this using a rather small search space, which led to fast optimization.

9 CONCLUSION

We have presented a new optimization method for recursive queries, which generalizes many previous optimizations described in the literature. We implemented it using a CEGIS and an EQSAT system. Our experiments have shown that this optimization is beneficial, regardless of what other optimizations a Datalog system supports. We discuss here some limitations and future work.

Our current implementation is restricted to linear programs, but our techniques apply to nonlinear programs as well. Non-linear programs require a more complex grammar \( \Sigma \); this is likely to increase the search space, and possibly increase the optimization time. We leave this exploration to future work.

Our current optimizer is heuristic-based, and future work needs to integrate it with a cost model. This, however, will be challenging, because very little work exists for estimating the cost of recursive queries. This paper applies a simple cost-model. We use the arity of the IDB predicate as a proxy for a simple asymptotic cost model, because \( N^{arity} \) is the size bound of the output, when \( N \) is the size of the active domain. This simple cost-model is currently used by the commercial DB system mentioned in the paper. If the optimized program reduces the arity, then it is assessed to have lower cost.

Two limitations of our current implementation are the fact that we currently do not “invent” new IDBs for the optimized query, and do not apply the FGH-optimizer repeatedly. Both would be required to support more advanced magic set optimizations.

Our initial motivation for this work came from a real application, which consists of a few hundred Datalog rules that were computationally very expensive, and required a significant amount of manual optimizations. Upon close examination, at a very high level, the manual optimization that we performed could be described, abstractly, as a sliding window optimization (WS in Fig. 10), which is one of the simplest instantiations of the FGH-rule. Yet, our current system is far from able to optimize automatically programs with hundreds of rules: we leave that for future work.
