## Abstract

Machine availability is a key indicator for the performance of the next generation of particle accelerators. Availability requirements need to be carefully considered during the design phase to achieve challenging objectives in different fields, as e.g. particle physics and material science. For existing and future High-Power facilities, such as ESS (European Spallation Source) and HL-LHC (High-Luminosity LHC), operation with unprecedented beam power requires highly dependable Machine Protection Systems (MPS) to avoid any damage-induced downtime. Due to the high complexity of accelerator systems, finding the optimal balance between equipment safety and accelerator availability is challenging. The MPS architecture, as well as the choice of electronic components, have a large influence on the achievable level of availability. In this thesis novel methods to address the availability of accelerators and their protection systems are presented. Examples of studies related to dependable MPS architectures are given in the thesis, both for Linear accelerators (Linac4, ESS) and circular particle colliders (LHC and HL-LHC). A study of suitable architectures for interlock systems of future availability-critical facilities is presented.

Different methods have been applied to assess the anticipated levels of accelerator availability. The thesis presents the prediction of the performance (integrated luminosity for a particle collider) of LHC and future LHC upgrades, based on a Monte Carlo model that allows reproducing a realistic timeline of LHC operation. This model does not only account for the contribution of MPS, but extends to all systems relevant for LHC operation. Results are extrapolated to LHC run 2, run 3 and HL-LHC to derive individual system requirements, based on the target integrated luminosity.

---

To Sergio, Irma and Giulia

## Acknowledgements

My sincere gratitude goes to professor Benedikt for giving me the opportunity of being enrolled as a PhD student at TU Wien. This has been for me an extremely valuable professional and personal experience.

The biggest 'thank you' goes to my CERN supervisor, R. Schmidt, who I consider my professional mentor and a great person. In these three years I had the chance of learning an incredible amount of things working with him. I've always felt free to work and take initiatives, being at the same time closely followed and guided. I will always be grateful for the constant support shown for the duration of my studies.

I would also like to thank all the other people working on Machine Protection (D. Wollmann, M. Zerlauth, J. Wenninger, A. Verweij, M. Jonker and many others) for the precious discussions during the past years and the constant availability to share their knowledge with students and colleagues. I believe this is one of the key ingredients of the success of CERN and in particular of our group.

Similarly I would like to thank B. Todd and L. Ponce for proposing me as a scientific secretary of the Availability Working Group (AWG). This was for me an important experience in a multidisciplinary domain and gave me the chance to learn a lot. I am convinced we will see during LHC run 2 the results of our efforts and studies over the last years.

I would like to thank A. Nordt for giving me the chance of collaborating on a challenging and interesting project as ESS. I particularly enjoyed being in Lund and getting to know a different working environment than CERN.

I would like to thank my office mates for the nice atmosphere we always had in the office and the support we gave to each other with daily questions and

doubts. A special mention is for the technical students I've been working with (Volkan, Jakub and Tobias): it has been a great pleasure and a great chance working with you. Following the work of other people definitely stimulates a deeper understanding of things also on the supervisor's side.

As last, but most important, I would like to thank my family.

Vorrei ringraziare mio padre Sergio, un irraggiungibile esempio dal punto di vista umano e un punto di riferimento costante della mia vita.

Vorrei ringraziare mia madre Irma per il suo infinito amore e il dispiacere ben celato per la lontananza di un figlio da ormai piú di 4 anni.

Ringrazio Giulia perché mi rende orgoglioso ogni giorno di essere suo fratello maggiore. Gli incredibili risultati universitari non sono altro che lo specchio di una maturità e una consapevolezza rara in una ragazza così giovane.

Infine ringrazio Irene per essere una donna straordinaria, gentile d'animo e allo stesso tempo forte come sarebbe difficile immaginare.

## Introduction

Machine availability and reliability are becoming key indicators for the performance of particle accelerators. In the future, optimizing accelerator availability will be fundamental in order to achieve the new challenging objectives of different facilities. For particle physics the aim is to fully exploit the potential of an accelerator for new discoveries. Furthermore, new user-oriented facilities are being designed to investigate open scientific questions regarding the microscopic structure of matter. Many synchrotron light sources are already operational around the world. Neutron scattering represents a complementary option for this type of studies. To produce the neutron beam, a proton beam is accelerated to high-energy (in the range of some GeV) in a linear accelerator. Neutrons are generated via a spallation process in a target made of a high-density material. Neutron beams are also of interest for the so-called Accelerator-Driven Systems (ADS), in which a sub-critical nuclear reactor is coupled with a particle accelerator. In such facilities the generated neutrons are used to sustain nuclear fission in a safer, more controlled way than in traditional reactors.

For the aforementioned accelerator applications the interest is to push beam performance to the limits. For particle physics studies, the number of interesting events recorded by the experiments depends on the collision rate and the collision energy, which in turn depend on the beam intensity (i.e. the number of particles in the beam) and energy. For neutron facilities, the neutron flux for user experiments depends on beam energy, intensity and the repetition rate at which the target is hit by the particle beam. In all facilities, the search for unparalleled beam performance leads to high

## 1. INTRODUCTION

---

stored power in the beams. This determines a significant damage potential in case of sudden and uncontrolled release of the beams.

For High-Power accelerators, operation with unprecedented beam power requires sophisticated Machine Protection Systems (MPS) to avoid any damage-induced downtime. Examples of high-power accelerators are the European Spallation Source (ESS, Lund, Sweden), the Large Hadron Collider (LHC, CERN, Geneva) and its upgrade to High-Luminosity LHC (HL-LHC). Machine protection systems make use of interlock systems to anticipate or mitigate the consequences of beam losses and other equipment failures. Upon the detection of a critical failure, the interlock system is responsible for bringing the accelerator in a safe state. The design of interlock systems has, thus, to be highly dependable to avoid damage of expensive equipment and unnecessary downtime of the facility. For the LHC, the damage in case of a catastrophic failure can cause damage beyond the possibility of repair.

Due to the high complexity of accelerator systems, finding the optimal balance between equipment safety and accelerator availability is challenging. On one hand machine protection systems preserve availability by preventing damage to accelerator equipment, on the other hand they reduce availability due to internal failures that can inhibit accelerator operation. The interlock system architecture, as well as the choice of the components to be used, have a large influence on the achievable level of dependability. Dedicated studies should therefore be performed in parallel to the design of machine protection systems. The studies should be consistently updated as the design evolves, considering all possible system dependencies on other systems and interactions with different users.

In this thesis novel methods to address the availability of accelerators and their protection systems are presented. Examples of studies related to existing interlock system architectures are given, both for linear accelerators and circular particle colliders. The challenge of designing new interlock architectures with demanding availability requirements extends to facilities other than particle accelerators, e.g. the International Thermonuclear Experimental Reactor (ITER). This aspect of interlock system design is addressed in detail in the following.

Based on the experience from the first run of the CERN's Large Hadron Collider (LHC), the thesis presents availability and performance predictions of the LHC and its

---

future upgrades. The performance of a particle collider is measured in terms of ‘integrated luminosity’, which is proportional to the number of interesting events recorded by the experiments.

The scope of this thesis is therefore to address the impact of availability on accelerator performance and quantify the gain that could be obtained by applying availability studies in different phases of the accelerator lifetime, from the conceptual design to its final exploitation.

Chapter 2 gives an overview of the facilities that will be taken as examples in the following for the application of availability studies. Both linear accelerators and circular colliders are considered.

Chapter 3 introduces the concept of availability for particle accelerators. An overview on the machine protection requirements and strategies for high-power particle accelerators is presented. The relationship between accelerator availability and machine protection is described in detail, as well as the tools used for availability tracking.

Chapter 4 describes the methodologies that are adopted for availability studies. The derivation of requirements for machine protection systems is performed with the System-Theoretic Process Analysis (STPA). An overview of the tools used for availability modelling is presented. It includes custom-developed Monte Carlo models, built for reproducing unique aspects of accelerator operation, as well as models built with commercially available tools.

Chapter 5 shows the application of an availability-driven design of MPS and its impact on interlock system architectures. Availability requirements for Linac4 are derived based on the STPA method. The adopted strategy to ensure high-dependability of machine protection systems is shown. The architecture of both Linac4 and ESS interlock systems is presented. A study on interlock system architectures for future availability-critical facilities is also presented. Results from these analyses allow giving clear guidelines for the design of future machine protection systems.

Chapter 6 addresses the problem of availability-driven optimization of accelerator performance. Data from LHC run 1 (2010-2012) is taken as a reference for LHC

## 1. INTRODUCTION

---

performance predictions. A Monte Carlo model of accelerator operation is used to quantify the impact of future operational scenarios on LHC performance, for future LHC runs and High-Luminosity LHC. The benefit of optimizing the time with colliding beams is also discussed.

Chapter 7 presents a summary of the described methodology and draws conclusions on the importance of availability for particle accelerators. Finally, the outlook on future applications of availability studies for particle accelerators is presented.

# Introduction to High-Power Particle Accelerators

## 2.1 The Large Hadron Collider (LHC)

The Large Hadron Collider (LHC) is the world's largest and most complex particle collider ever built. Its 27 km circumference is housed in a tunnel, about 100 m underground, in the area below the French-Swiss border close to Geneva (Fig. 2.1). The LHC has four main experiments (ATLAS, CMS, ALICE, LHCb) aimed at studying the open mysteries of the universe, from the discovery of the missing pieces of the standard model, to super-symmetry. The recent history of the LHC culminated in 2012 with the announcement of the discovery of a new particle of the standard model, the Higgs boson (1) (2).

The history of the LHC dates back in 1984, when the first concept of a new accelerator was proposed to replace the existing Large Electron-Positron Collider (LEP) (3). The idea behind the LHC was to build a machine capable to reach unprecedented energies and intensities for more efficient particle collisions, resulting in an increased number of statistics for physics experiments in unexplored ranges of energies. The dream of building such a machine had nevertheless to face major technological challenges, from the design of 9 T superconducting magnets to the development of suitable Machine Protection Systems (MPS). The LHC is in fact one of the first particle accelerators with damage potential beyond repair. The cost of repair and replacement of some LHC systems (e.g. magnets) is in fact so high that a major failure of the LHC,

## 2. INTRODUCTION TO HIGH-POWER PARTICLE ACCELERATORS

---

**Figure 2.1:** The Large Hadron Collider (LHC).

resulting in extensive damage of equipment in the tunnel, could not be faced, probably compromising particle physics studies on a worldwide scale.

The commissioning and tests in situ of LHC systems started in 2008. In September 2008 an accident involving the magnet powering system was the cause of one year of forced downtime for the replacement of several magnets in the tunnel (4). It was discovered that the splices of the superconducting busbars (NbTi plus copper as a stabilizer) feeding the magnets could have manufacturing defects in the copper electrical continuity. This prevents the correct current flow in case of local loss of superconductivity (quench). Thanks to the prompt reaction to the accident and the design of new electronics to cope with the newly discovered failure mode, LHC operation was resumed in 2009. For safety reasons it was decided to limit the energy from the nominal target of 7 TeV per beam to 3.5 TeV per beam. In 2010 the first significant achievements of the LHC were reached, with the first collisions at 3.5 TeV.

The performance of the LHC is defined in terms of the integrated luminosity delivered to the experiments. This quantity gives a measure of the number of relevant events observed at the experiments, i.e. the production of rare particles as the Higgs

## 2.1 The Large Hadron Collider (LHC)

Boson. Luminosity is measured in inverse barn [ $b^{-1}$ ] and more practically for the LHC in inverse femtobarn  $fb^{-1}$ . The 2011 and 2012 runs were very successful and the LHC was able to deliver about  $30 fb^{-1}$  to the main experiments over its first three years of proton run. The LHC is not only capable of performing proton-proton collisions. A running period during the year is also dedicated to proton-ion (lead) collisions or ion-ion collisions.

The success of the LHC has to be retraced also in the performance of its injectors (Fig. 2.2). The beam produced by the Linac2 is accelerated in the Proton Synchrotron Booster (PSB), the Proton Synchrotron (PS), then injected in the Super Proton Synchrotron (SPS) before finally reaching the LHC.

**Figure 2.2:** A schematic view of the CERN accelerator complex. The proton beam is produced and accelerated by Linac2 and injected into the four rings of the Proton Synchrotron Booster (PSB). The beam is then recombined and injected in the Proton Synchrotron (PS) and then in the Super Proton Synchrotron (SPS). At the energy of 450 GeV the beam can finally be extracted towards the LHC, with dedicated 3 km long transfer lines.

In the years 2013 and 2014 the LHC underwent a period of extensive maintenance and consolidation, the so-called Long Shutdown 1 (LS1) (5). All the outstanding failure modes affecting LHC operation during run 1 were mitigated. The largest efforts

## 2. INTRODUCTION TO HIGH-POWER PARTICLE ACCELERATORS

during the LS1 were devoted to consolidate the discovered imperfections in the copper continuity of the superconducting busbars. Careful quality insurance procedures were put in place to prepare the LHC restart, foreseen in April 2015. The machine will thus be able to resume operation with increased energy, 6.5 TeV as compared to 3.5 TeV in 2010. This will ensure increased statistics for the experiments and offer the potential for new discoveries. During the LS1, significant changes have been introduced in the machine and will require a progressive recovery of stable operation, on the base of what was achieved in 2012. Only then, it will be possible to tune and optimize LHC operation, based on the experience collected during the LHC run 1.

### 2.2 LHC Injectors Upgrades and LHC Upgrades

The LHC performance is directly influenced by the performance of its injectors. To push the LHC to its limits in terms of beam brightness and luminosity production, significant upgrades of the LHC and of its injector chain are required. The LHC Injectors Upgrade Project (LIU) was launched at CERN to guarantee the required beam characteristics for increased LHC performance (6). All the injectors will require consolidations and upgrades to reach the ambitious LHC goals. In particular the existing Linac2, the first element in the injector chain, will be replaced by the Linac4. Linac4 is an  $H^-$  linear accelerator with an output energy of 160 MeV, whose goal is to provide beam brightness out of the PSB increased by a factor 2 compared to the currently achieved values. Linac4 has entered the commissioning phase in 2013 and will be connected to the PSB by a dedicated transfer line after the Long Shutdown 2 (2019).

Efforts invested in the injectors will only be part of the necessary modifications. The High-Luminosity LHC Project (HL-LHC) was launched with the scope of increasing LHC integrated luminosity by a factor 10 beyond the design value (7). Significant hardware upgrades will be required, for both experiments and accelerator equipment. The use of new technologies for different applications was the base for a large research and development campaign. As an example, new superconducting  $Nb_3Sn$  magnets are currently under study to replace the existing ones close to the Interaction Points (IPs). The use of crab cavities will ensure perfect overlapping of colliding bunches and will improve luminosity production. Such changes will have huge implications on the machine, that will require newly designed optics and MPS, amongst others. Also

## 2.3 The European Spallation Source (ESS)

---

operational practices will be influenced by these changes. The exploitation of luminosity leveling will be the baseline for HL-LHC operation. This practice consists in keeping the instantaneous luminosity constant at the beginning of the collisions to limit event pile-up for the particle detectors, i.e. the maximum number of simultaneous interesting events that can be ‘seen’ by the detector. Such technique will have to be mastered during LHC run 2 in preparation for the HL-LHC run in 2025. The addition of many changes to the existing LHC, both regarding the hardware and the beam parameters, may have a significant impact on machine availability, which will be a crucial figure for the success of the HL-LHC project.

**Figure 2.3:** The European Spallation Source (ESS).

## 2.3 The European Spallation Source (ESS)

The European Spallation Source (ESS) is an accelerator-based facility for scientific experiments with neutron beams (8). It is currently under construction in Lund, Sweden (Fig. 2.3). The construction will end in 2017 and the first neutron beams will be produced in 2019. Neutron methods allow studies on the molecular composition of matter that no other techniques can provide. Neutrons have low probability of interaction with most materials and this allows precise and sensitive quantitative analyses.

## **2. INTRODUCTION TO HIGH-POWER PARTICLE ACCELERATORS**

In addition neutrons allow studying samples even under extremely low temperature conditions. Due to their neutral charge, neutrons offer the possibility to investigate the microscopic magnetic structure of matter. The goal of neutron science is to study properties of assemblies at scales which are small enough to exhibit quantum effects. Such studies may give new insights towards a deeper understanding of nature and open new prospects for technological progress in many fields. As an example the search for renewable energy sources will benefit for detailed analyses of materials for solar cells, batteries and much more. In the health domain, neutron science provides the means for analyses on materials for implants and drug delivery systems, amongst others.

The ESS will accelerate proton beams in a linear accelerator up to 2 GeV, featuring both normal conducting and superconducting cavities, and guide them to a tungsten target for the production of neutrons through a spallation process. Neutron beams will be guided to different user experiments, covering a wide spectrum of applications and research. The design of ESS will enable unparalleled high neutron brightness and a unique long-pulse structure, with neutron pulses of 2.86 ms at low-frequency (14 Hz). The nominal average beam power of ESS will reach 5 MW per pulse (125 MW peak power), which is at least a factor five times higher than for similar existing facilities in the world, as the Spallation Neutron Source, SNS (9).

# 3

## Availability Requirements for High-Power Particle Accelerators

In the present chapter the definition of availability in the context of particle accelerators is presented. The focus of the work is on high-power particle accelerators, for which the importance of availability is discussed. A description of the relationship between accelerator availability and MPS is given, for different types of machines.

### 3.1 Availability metrics

The definition of availability in the context of accelerator facilities is often subject to interpretations, as different types of machines and operational modes lead to different definitions. In this paragraph three definitions of availability are proposed and should apply to most particle accelerators.

A common definition of availability in literature is taken as a reference (10):

*“The availability is the probability that a system is in a functional condition at the time  $t$  or during a defined time span, under the condition that it is operated and maintained correctly.”*

Different definitions of availability arise from the interpretation of the term “functional“ in the context of particle accelerators. If the above definition would be used, an accelerator could be defined functional if all the related sub-systems are ready for

### 3. AVAILABILITY REQUIREMENTS FOR HIGH-POWER PARTICLE ACCELERATORS

---

operation. Nonetheless this is not a sufficient condition for availability from an experimental perspective. A circular accelerator like the LHC, besides being functional, requires beams injected from the SPS in order to serve its experiments. What is common to different types of accelerators is the need for a 'setup' time in order to reach the nominal conditions (particle energy, intensity, beam-size) before being able to deliver beams to the experiments or to the next accelerators. This time varies widely depending on the machine type, from some minutes to several hours.

The following quantities are defined for a particle accelerator:

**Run Time (RT):** scheduled operational time of the accelerator.

**Fault Time (FT):** time needed to clear a system fault, i.e. the time elapsed between the fault occurrence and the time when accelerator operation is not inhibited by the fault. This eventually includes the time to contact system experts for diagnostics and the logistics time if an intervention is necessary, in addition to the actual recovery time of the systems.

**Turnaround Time (TT):** time needed to achieve nominal operating conditions of the accelerator, when no faults occur.

**Beam Delivery Time (DT):** effective time for beam delivery to experiments or other accelerators.

Based on these quantities, two definitions of availability can be given:

**Beam Availability (BA):** it is the probability that an accelerator can be operated with beam at time  $t$  ( $BA = \frac{TT+DT}{RT}$ , assuming that beam could be provided to the accelerator).

**Availability for Physics (PA) or Physics Efficiency:** it is the probability that an accelerator provides beam to the experiments for measurements or to the next accelerators ( $PA = \frac{DT}{RT}$ , assuming that beam could be provided to the accelerator).

The underlying assumption for these two definitions is that beam is present in the accelerator, i.e. these are strictly related to an experimental perspective. Accelerators are nevertheless operated even without beam, e.g. for commissioning and tests. A third definition of availability is therefore given from an equipment perspective:

## 3.2 Availability-Critical Particle Accelerators

---

**Machine Availability (MA):** it is the probability that an accelerator can be operated at time  $t$ , even without beam ( $MA = \frac{RT-FT}{RT}$ , even without beam in the accelerator).

The status of individual accelerator systems is transparent to the previous definitions, as long as it doesn't impact accelerator operation. Some systems could be operated even in a degraded mode, still not compromising Machine Availability. It could be for example acceptable to have a temporary loss of redundancy in a MPS. In a Linac, operation could be carried out without a faulty RF cavity, following the necessary deconditioning and compensations (11). For individual accelerator systems the general definition of availability from literature can be used.

The following inequality holds for the given quantities:

$$PA < BA \leq MA \tag{3.1}$$

Where the equality sign is only theoretical, as it would be verified only in case no commissioning nor machine tests would be executed during the accelerator run.

All the three availabilities are relevant for accelerator performance. In particular for the evaluation of the experimental outcome of the accelerator run, the Availability for Physics is the parameter to optimize. This must be achieved by increasing the beam delivery time, either by reducing the fault frequency, decreasing the fault time or optimizing the turnaround time.

## 3.2 Availability-Critical Particle Accelerators

Traditionally not all particle accelerators are considered as 'availability critical'. Only user-oriented facilities as synchrotron light sources and medical accelerators are designed with strict availability requirements. In such cases availability is a crucial aspect for the success of the facility. Both the number of users and the related income of the facility can be significantly compromised if the target level of availability would not be reached. The costs to be faced to overcome design bottlenecks having an impact on availability can be so high that it could result more convenient suspending accelerator operation rather than going through such process of redesign. Future machines and

### 3. AVAILABILITY REQUIREMENTS FOR HIGH-POWER PARTICLE ACCELERATORS

---

Accelerator Driven-Systems (ADS) (12) will have even more demanding requirements in this respect.

In this thesis it will be shown that high-power particle accelerators should be considered as availability critical facilities, given their large damage and downtime potential. In order to reach the challenging goals of newly designed accelerators and accelerator systems, emphasis must be put on availability-driven design from the beginning of a project. This practice allows considering all relevant aspects for machine performance and work towards optimized exploitation of the facility.

**Figure 3.1:** Integrated Luminosity production recorded by the ATLAS experiment at CERN in 2011 and 2012.

The first LHC run (2010-2012) is a good example of the impact of availability optimization and increasing machine understanding on accelerator performance. Fig. 3.1 shows the integrated luminosity over time during the 2011 and 2012 runs of the LHC (13). It can be seen that a significant increase of the integrated luminosity can be observed in the years 2011 and 2012. Many factors play an important role in this respect. The acquired understanding of beam-related phenomena, as beam losses and

## 3.2 Availability-Critical Particle Accelerators

---

instabilities, and the consolidation of operational procedures, e.g. improvement of beam injection, and increased beam parameters (energy and intensity), are all important factors towards higher luminosity.

Increased availability is also directly influencing the luminosity production. The Availability for Physics amounted to 32% in 2011 and to 36% in 2012 (14). Even if complex dependencies exist among beam parameters, fault occurrence and machine availability, this picture is used to qualitatively show that availability is one of the factors that directly translates in higher scientific outcome of an accelerator based-facility. In the past the most efficient way to increase the integrated luminosity of a collider for example was to increase the peak luminosity. For the LHC nowadays the limit to the maximum peak luminosity is imposed by the number of pile-up events per bunch crossing in the experiments, i.e. the number of interactions per bunch crossing (15). Alternative ways to increase the integrated luminosity should therefore be explored.

**High-Luminosity LHC (HL-LHC)** High-Luminosity LHC is the CERN project aiming at the production of  $3000 \text{ fb}^{-1}$  over ten years of HL-LHC run (16), starting from 2025. Major changes in the machine will be required to achieve such challenging goals. The so-called crab cavities (17) will be installed to improve the efficiency of beam collisions. New superconducting magnets (18) in the beam interaction regions are under design. Feasibility studies of High-Temperature Superconducting (HTS) links for magnet powering are ongoing to ensure long-term operation of equipment in a radiation-free environment (19). A new generation of electronic systems for equipment protection is under study. This will have to cope with increased radiation levels and failure modes associated to the new systems, still assuring the same level of protection. A new collimation system is under development to limit beam losses to the same levels of LHC run 1 (20). The significant increase of luminosity will determine an increase of the thermal load on the magnets at the interaction points. New cryo-plants will be installed to decouple such magnets from the rest of the sector magnets (21). The same strategy applies to the superconducting cavities in the LHC point 4, which will also be decoupled from the sector cryogenic system. In the HL-LHC era machine performance will be pushed to the limits and stress levels on components will be unprecedented. Considering availability as a crucial requirement for the design of these systems is vital

### 3. AVAILABILITY REQUIREMENTS FOR HIGH-POWER PARTICLE ACCELERATORS

---

for the achievement of the project goals. Requirements for the availability of HL-LHC have to be expressed in terms of a tolerable yearly failure budget per system in order to reach  $300 \text{ fb}^{-1}$ . Details on this subject will be given in Chapter 6 of this thesis.

**Linac4** Linac4 is the linear accelerator that will provide proton beams to the CERN complex from 2019, replacing the existing Linac2 (22). Linac2 is operating since 1978 with excellent availability performance (98 % Availability for Physics). Linac4 will accelerate H<sup>-</sup> ions from the source up to the injection in a dedicated transfer line at 160 MeV. Electrons will be stripped at the injection in the PSB by dedicated stripping foils (23). This is a common practice for other accelerators in the world (24), but experience will have to be gained at CERN in this respect. Linac4 will reach 160 MeV, as compared to 50 MeV from Linac2. Even low energy, low power beams have significant damage potential, as delicate equipment can be damaged due to the beam energy deposition confined over very small volumes. Accidents could result in significant downtime of the Linac, which would compromise the activity of all accelerators in the CERN complex. To prevent the occurrence of such accidents a new interlock system based on LHC experience has been designed and is already operational during the commissioning of Linac4. The goal of the interlock system is to prevent beam-induced damage to equipment, while minimizing the number of spurious beam stops due to false triggers. At the same time, beam delivery to the different destinations and experiments must be optimized. The target for Availability for Physics of Linac4 has been set to 95 %.

**The European Spallation Source (ESS)** ESS operation aims at delivering bright neutron beams to user experiments. From the user perspective, the ESS is the most similar machine to synchrotron light sources and medical accelerators. The requirements for high-availability directly reflect this user-oriented approach. These can be summarized as follows, assuming that a failure occurs when the accelerator provides a beam of less than 50 % of the nominal power for more than 1 minute:

**Reliability:** 95.5 % probability of not having a failure over 1 hour period.

**Availability for Physics:** 95 % of uptime over the scheduled yearly time for operation.

## 3.2 Availability-Critical Particle Accelerators

---

ESS will face the challenge of combining the complexity of accelerator design with that of the design of the target and of the neutron instruments. Damage to any of these elements would result in major costs for repair and downtime, therefore the MPS will play a crucial role to ensure safe operation. Suitable maintenance strategies and design measures will have to be chosen to cope with these effects. Neutrons will be produced by a spallation process, generated by a proton beam impacting on a helium cooled tungsten target, rotating at 14 Hz. If the 5 MW beam would hit the target repetitively in the same spot for example, the damage limit would be reached in less than 10 beam pulses. A rastering system ensures that the target will only be hit in the same area at a predefined maximum frequency. This is achieved by partitioning the target into segments and by directing different proton bunches towards different points of a segment.

**The Future Circular Collider** The recent discoveries of the LHC opened new perspectives for the design of the next generation of particle accelerators. The success of the first LHC run gave a strong push to the design of particle accelerators aiming at higher centre-of-mass energies. The preliminary studies for the design of a Future Circular Collider (FCC) have therefore begun at CERN in January 2014 (25). Several options for this machine are being discussed (p-p, e+e-). The FCC p-p has a target of 100 TeV centre-of-mass energy. Assuming that the technology of 16 T  $Nb_3Sn$  dipoles will be available for large scale production, such a machine would have a circumference of about 100 km. Two proton experiments and two additional special-purpose experiments are foreseen and the machine will be designed for a peak luminosity of  $5 * 10^{34} cm^{-2} s^{-1}$ . Besides the research and development needed for the future technologies in the different fields, one of the challenges of the FCC will be the dependability of its systems. Given the complexity and the wide variety of systems involved (electronic, mechanical, software), reliability and maintainability of such systems will be crucial aspects for the success of the FCC. Maintenance and repair strategies will have a huge impact on the scientific outcome of the machine, as logistic time will be one of the dominating parameters in the downtime, considering the unprecedented dimensions of the machine. To enforce safety and availability constraints a complex and distributed Machine Protection System (MPS) has to be designed. Dependability studies for the future MPS, as well as for other relevant accelerator systems, are necessary to assess the

### 3. AVAILABILITY REQUIREMENTS FOR HIGH-POWER PARTICLE ACCELERATORS

---

feasibility of the project. Complex extrapolations on the current technologies for electronics and accelerator systems should be carried out (26). As an example, commercial electronic systems are nowadays far from reaching the required level of complexity.

#### 3.3 The Need for Machine Protection Systems (MPS)

In high-power particle accelerators the damage potential is determined by the energy stored in the beams and by the timescale for the release of such energy. The damage potential for large storage rings is primarily associated to the very high beam stored energies (e.g. 362 MJ for LHC nominal parameters, over one LHC turn of 89  $\mu$ s). For pulsed Linacs it is instead related to the high beam currents and repetition rates. In case superconducting magnets are used, the powering system is also a source of large stored energy and, hence, damage potential. A sudden and uncontrolled release of these stored energies can provoke major damage of accelerator equipment. This both implies enormous costs for repair and a downtime of the facility for an extended period of time. The downtime depends on the damage level, availability of spare components and personnel resources. The focus of MPS for particle accelerators is thus devoted to protection of equipment. Personnel and environmental protection are outside the scope of MPS. The term 'safety' will be used in the following referring to 'machine safety'.

The objectives of MPS can be listed as follows:

1. Protect the machine (safety)
2. Protect the beam (availability)
3. Provide the evidence and diagnostics (maintainability)

A sophisticated MPS is necessary to cope with stringent safety requirements. The probability of a missed detection of a dangerous machine configuration can result in major damage of equipment and should therefore be minimized. For MPS it is mandatory to have designs based on fail-safe architectures. This implies that a failure of the MPS should always result in an action taking the machine to a safe state. Safety-critical features should be redundant and implemented in hardware. Risks are not only associated to component unreliability, but can result from unforeseen interactions or modifications

### 3.3 The Need for Machine Protection Systems (MPS)

---

of the designed systems. As an example, critical parameters should only be changed according to predefined procedures and not remotely. All these considerations contribute to ‘protect the machine’ (1). The implementation of a complex MPS is nevertheless also subject to failures. The aim of the MPS is ideally to be transparent with respect to machine operation and to act only when critical failures occur. Every time an internal failure of the MPS is detected, an action is taken to prevent the uncontrolled release of stored energies in the beams and in the magnets. This action prevents normal beam operation of the accelerator, i.e. it compromises availability (‘false dump’). Beam operation has to be ‘protected’ by an excessive number of MPS failures (2, ‘Protect the beam’). Finally, powerful diagnostics should be deployed for efficient follow-up and understanding of all machine failures in order to verify the correct functionality of the MPS (3, ‘Provide the evidence’).

Modern accelerators require both passive protection and active protection to cope with all possible failure scenarios. Passive elements, as absorbers, dumps and collimators, are used to protect the accelerator when the timescale of the failures is too small to be handled by the active protection layer. For particular failure cases, beam losses can develop in very short timescales. In general losses occurring in the ns to  $\mu\text{s}$  scale can only be handled by passive devices, whereas losses going from several tens of  $\mu\text{s}$  to seconds can be managed by the active protection. The latter consists in a distributed electronic system monitoring relevant quantities to anticipate or identify potentially dangerous machine configurations and allow acting on the beams and on the magnet powering system before an accident can occur. The strategy for the actuation of an emergency action depends on the machine and its layout.

Protecting the machine from beam-induced damage requires dedicated analyses of beam loss patterns and material damage. Energy, intensity, beam size and loss distributions and timescales are all important figures to consider when evaluating the damage potential of a failure scenario. Simulations of energy deposition in different materials, as well as material damage experiments, should be carried out to estimate the damage limits. In the case of superconducting magnets and cavities, this applies also to the definition of beam-induced quench levels (27). The impact of long-term effects of radiation on materials should also be quantified for an assessment of the lifetime of components.

### 3. AVAILABILITY REQUIREMENTS FOR HIGH-POWER PARTICLE ACCELERATORS

---

#### 3.3.1 Protect the Machine: MPS for circular accelerators

Thanks to their layout, circular accelerators have the possibility of reaching the highest beam energies, as particles can be accelerated by the same RF cavities at every passage in the ring. The LHC will be taken here as an example to illustrate general concepts that apply for all circular accelerators (28). For the LHC, the particle energy per beam is 7 TeV and the total number of protons (i.e. the beam intensity) is  $3.2 \times 10^{14}$ . This results in a maximum stored energy of 362 MJ per beam. A circular accelerator is usually subdivided in sectors for independent powering. The use of this powering scheme in the LHC allows limiting the stored energy in the magnets to about 1.1 GJ for each of the 8 sectors (29). In a circular accelerator, straight sections housing relevant accelerator equipment are alternated with bending sections dominated by the presence of magnets (dipoles, quadrupoles and higher order correctors). For the LHC, each of the straight sections has a well defined role. Points 1, 2, 5 and 8 of the LHC house the experiments and their detectors. Point 3 and 7 the collimation system. Point 4 the RF cavities and equipment and point 6 the beam dumping system (Fig. 3.2).

**Figure 3.2:** Layout of the CERN LHC.

The action which is taken in case a failure is detected is to extract the beam from the ring towards a dumping absorber, i.e. to trigger a ‘beam dump’. Beam injection from previous accelerators in the injector chain is also inhibited. The beam dumping system

### 3.3 The Need for Machine Protection Systems (MPS)

---

(30) is located in point 6, thus the beams always have to reach this point before being able to be safely extracted. Special magnets, called kickers, have fast rising magnetic fields to deflect the beam towards the beam dump. The current rise time of the kickers is  $3 \mu\text{s}$ , therefore a particle-free gap (abort gap) of the same duration must be left in the beam to avoid significant losses while extracting the beams. Once extracted, the beam is defocused to reduce its energy density and guided towards the beam dump, the only element in the machine capable of withstanding a full beam impact.

The fault detection is initiated by different types of sensors that communicate to a central distributed system, the Beam Interlock System (BIS) (31). Beam losses for example are monitored with Beam Loss Monitors (BLMs, Fig. 3.3, (32)). These devices measure the ionization produced in a gas by the scattered lost particles from the beam trajectory. They consist of a ionization chamber filled with a noble gas (e.g. Argon) and electronics able to readout the signal produced by the ionization chamber. The signal is compared with predefined thresholds for the identification of dangerous beam losses. The fastest reaction time of the BLM system is  $40 \mu\text{s}$ .

**Figure 3.3:** LHC Beam Loss Monitors placed on the side of superconducting quadrupoles.

The BIS is in charge of gathering signals coming from local equipment surveillance and trigger a beam dump in case it recognizes a dangerous machine configuration. This system is highly critical and must be designed for high dependability (33). The challenge in this case is having a dependable and distributed system over the machine circumference. The beam dumping system (LBDS) is the most critical system of the

### 3.3 The Need for Machine Protection Systems (MPS)

---

Furthermore in case of a quench, both active and passive protection measures can be put in place. The natural development of a voltage in the superconducting magnets is sufficient to activate cold diodes that allow bypassing the quenching area (passive). At the same time, to reduce the energy density of the quench, this needs to be spread over a larger surface in the magnet. This can be achieved with the so-called quench heaters or with the innovative Coupling Loss Induced Quench (CLIQ) (active) (39), currently under study at CERN. In the first case, a quench of the all magnet is induced by forcing a current to flow in dedicated strips placed on top of magnet coils. The CLIQ is instead based on an induced oscillation of the transport current in the coils, that generates locally a fast variation of the magnetic field, which in turn translates into a high coupling current loss that allows a fast spread of the quench in the magnet.

#### 3.3.2 Protect the Machine: MPS for linear accelerators

From the MPS point of view the main difference between Linacs and circular machines is that in Linacs the beam only passes once in the accelerator, therefore the possibility to safely extract it in case of failures is reduced. Linacs use different ‘actuators’ to stop beam operation in the low-energy section and prevent beam propagation to higher energies. The fraction of the beam that overcomes the actuators is transmitted to the end of the Linac or is lost without the possibility of being stopped. The first option to stop beam transmission in the Linac is to inhibit its production from the particle source. Depending on the design, triggering a shutdown of the source can compromise its stability and impact on the turnaround time. The protection function is therefore mainly implemented by dedicated components, the so-called choppers (40). These components are used for normal operation to define the temporal beam structure, namely the beam pulse length. They consist of electrostatic plates that deflect the beam trajectory towards passive absorbers by the activation of a high-voltage pulse. In case a failure is detected, they can be used to deflect the beam and prevent its transmission. In the case of Linacs, it is therefore more appropriate to speak about a ‘beam stop’ rather than a ‘beam dump’. Depending on the machine layout and beam parameters, the beam power in the low energy section of a Linac can already reach the damage level of materials (see A.1). More than one chopper can be used as actuator of the MPS, at different locations of the Linac, both for ensuring redundancy of the actuation function and to limit the beam power deposited in the absorbers. The choppers have an

### 3. AVAILABILITY REQUIREMENTS FOR HIGH-POWER PARTICLE ACCELERATORS

---

intrinsic field rise time necessary to reach the required deflection. Such rise time should be minimised, depending on the timescales over which damage could occur. During the time that goes from a failure detection to the activation of an actuator by the MPS the beam is not deflected and is propagated to the higher-energy sections of the Linac, potentially being lost under dangerous conditions.

The detection of beam losses in a Linac is performed with two different methods. As for circular machines, BLMs are used, depending on the energy reached by the Linac. Depending on the particle type and impact angle, BLMs are only capable of detecting losses through the ionization process from a given energy. Assuming protons and an impact parallel to the BLM axis, protons give a significant response only above 50-100 MeV (41). In the low-energy section alternative methods must therefore be implemented. Beam Current Monitors (BCMs) are used to measure the beam current at different locations of the Linac and compare the beam transmission (42). If a poor transmission is detected this implies that beam losses occur between the two reference BCMs and beam operation needs to be stopped.

Beam losses in Linacs can also be the cause of phenomena which cannot be observed in other types of machines. As an example, 'errant beams' (43) can be the cause of progressive degradation of cavity performance. This is a consequence of beam losses in the superconducting cavities that contribute to build-up a favourable environment for arcing, leading to possible damage of the cavity surface. In the worst case the replacement of a cavity module can be necessary and take up to several weeks (44). Monitoring beam losses originated in the warm section of the Linac can contribute to prevent the occurrence of such failure mode.

#### 3.3.3 Provide the Evidence: The Post-Mortem System

For a complex machine like a particle accelerator, it is of vital importance to be able to perform off-line analyses of observed phenomena occurring during the accelerator run. A thorough understanding of the machine, the interaction among its components and the sensitivity of its behaviour to relevant parameters is necessary towards performance optimization. For the LHC for example, it is of particular interest to analyse events which are relevant for machine protection, as magnet quenches, beam losses, Unidentified Falling Objects (UFOs, (45)) and Single Event Upsets (SEU) due to radiation to electronics (R2E). UFOs are charged dust particles (e.g. soot or thermal-insulation

### 3.3 The Need for Machine Protection Systems (MPS)

---

fragments) that can interact with the beam (46), generating losses which are detected via the BLM system. SEUs are random failure events caused by the effects of radiation on electronic systems. A SEU consists in a bit flip induced in a digital element due to an ionizing particle (47). No permanent damage is induced as the bit can be rewritten. A SEU on bits carrying sensitive information can lead to unnecessary beam dumps.

As shown in this thesis, detailed analyses of these phenomena allow for a more efficient balance between machine safety and availability. A system gathering information for such analyses should therefore be designed and foreseen from the beginning of operation, to learn from the experience gained at every stage of the machine lifetime. Capturing this information for a very complex machine poses the challenge of the collection of high-quality data. At CERN a Post-Mortem system (PM) was developed for capturing data coming from the LHC in case a beam dump is issued (48). A snapshot of the status of the different systems is recorded every time the beams are dumped in order to retrace the root cause initiating the beam dump. This allows the verification of the correct functionality of individual systems and is particularly important to verify the correct functionality of the MPS. A series of dedicated post-operational checks are automatically carried out on MPS for this purpose.

#### 3.3.4 Provide the Evidence: The Accelerator Fault Tracking (AFT)

Analysing the occurrence and root cause of beam aborts does not give a full overview of the relevant quantities for consistent availability studies of an accelerator. Fig. 3.5 shows a visual representation of the relevant quantities for availability tracking for the LHC (49).

The horizontal axis shows the LHC run time. The accelerator mode and an entry indicating if the machine is in access for interventions are shown in the top part of the picture. Particle energy (black) and beam intensities (blue and red) are also given. The characteristic trend of these quantities led to the naming of this visualization as the ‘cardiogram of LHC operation’. The green lines indicate the time for experiment data-taking and purple crosses PM events. Red lines instead indicate equipment faults, sorted by accelerator system. Such visualization was produced ‘manually’ by combining entries from different databases for the first LHC run and yielded significant hints for the identification of variables and parameter towards efficient fault tracking. As a consequence, a project was launched at CERN to develop an online system for capturing

### 3. AVAILABILITY REQUIREMENTS FOR HIGH-POWER PARTICLE ACCELERATORS

Figure 3.5: 'Cardiogram' of LHC operation.

### 3.3 The Need for Machine Protection Systems (MPS)

---

fault data during operation (50). This is a fundamental tool for availability studies, providing dynamic fault and turnaround time distributions from the beginning of LHC run 2 in 2015. As will be explained in par. 6.2.2, modelling the dependency of accelerator performance on availability allows identifying the weaknesses of machine operation and the areas where the investment of new resources would bring the biggest benefit for luminosity production. During the first LHC run fault data analyses have been carried out independently by working groups focusing on different aspects of accelerator performance (e.g. R2E). Getting a consistent picture of all relevant dependencies on beam parameters and operational choices is very difficult without dedicated tools in place. At the same time a full automation for gathering fault data may not be ideal. The root cause of particular failure events can be discovered only after careful expert analyses, which can take up to several weeks. Currently there are few failure events from the first LHC run for which the root cause is still unidentified. A continuous effort to maintain a consistent view on accelerator faults should be foreseen.

## 4

# Methods for estimating the Availability of Particle Accelerators

Chapter 4 presents an overview on the methods used in Chapters 5 and 6 for availability-driven design of MPS and performance optimization for particle accelerators. This thesis shows that availability is a key parameter for particle accelerators, from the design phase to the final exploitation. A top-down approach to availability driven design is more suitable for early design stages of a project. For individual system design, as well as for newly introduced systems in an operating machine, a bottom-up approach can be more convenient. The System-Theoretic Process Analysis (STPA) is therefore chosen for early hazard analyses and to derive requirements for individual systems. Dedicated studies, triggered by the STPA procedure, can be used to address particular aspects of the design. Due to the complexity of the systems under study, availability modelling has been mostly based on Monte Carlo simulations, rather than analytical calculations. The adopted simulation environments are MATLAB (51) and Isograph (52).

### 4.1 System-Theoretic Process Analysis (STPA)

STPA is a novel hazard analysis technique that applies the principles of systems theory to the design of safety-critical systems (53).

#### 4. METHODS FOR ESTIMATING THE AVAILABILITY OF PARTICLE ACCELERATORS

---

Traditional hazard analysis techniques are based on the assumption that failures and interactions in a system occur randomly. This inevitably leads to a reactive approach to hazard management. Nowadays, the concurrent use of hardware, software and mechanical components is diffused in a wide variety of domains. System complexity is thus a crucial aspect to be taken into account when dealing with hazard analyses. For a complex system as a particle accelerator the assumption of event randomness leading to an accident is not appropriate. The goal of the hazard analysis shifts towards finding patterns and conditions leading to accidents, in order to identify proactive measures to mitigate or eliminate them. This concept is based on the research of 'systemic causes' of accidents, as opposed to traditional causality models, which assume that an accident is the result of a chain of events leading to a loss (Chain-of-Events model or Swiss Cheese model). Such events are mostly failures of system components (hardware, software, humans). In this perspective, it is natural to think that increasing the system safety can be achieved by increasing components' reliability and by interrupting the chain of events with additional measures. In a complex environment, events leading to accidents have to be interpreted as uncontrolled interactions or behavioural events. The system is seen as a hierarchical structure of levels. Each level manages the relationships of the next lower level of the hierarchy, by imposing constraints on the behaviour and interactions of its components. STAMP (System-Theoretic Accident Model and Processes) is an accident model based on systems theory for which safety is an emergent property relative to the interaction of components with a larger environment. An accident occurs when the constraints imposed at a given level of the hierarchy are violated (are insufficient) by component interactions. The role of safety engineering therefore regards the enforcement of safety constraints to control the behaviour of the overall system. This is achieved through hierarchical safety control structures, i.e. control structures that operate from one level to the other. Each controller has a logic or algorithm to decide what action needs to be provided to the lower level (or process) to enforce the constraints. As from control theory, such algorithm has to be 'informed' of the state of process, based on a process model. Assuming that a safety-control structure exists, then an accident occurs due to (53):

1. Unhandled environmental disturbances or conditions
2. Unhandled or uncontrolled component failures

## 4.1 System-Theoretic Process Analysis (STPA)

---

3. Unsafe interactions among components
4. Inadequately coordinated control actions by multiple controllers

STPA has its foundation in the STAMP accident causality model. Thus it does not produce probabilistic assessments of risks and accident occurrence, but allows identifying more effectively hazards related to software, human behaviour and design processes. The advantage of STPA over traditional hazard-analysis methods is that it can be used since early design stages. It follows a top-down approach for the design of safety control structures, starting from the definition of high-level safety requirements and corresponding constraints. The latter can be refined as the design progresses and translated into more detailed requirements for components belonging to lower abstraction levels. This allows an iterative design, which reduces the risk of facing enormous costs of re-engineering in case major changes are found necessary late in the design. It has to be noted that the basic principle of STPA is very general and allows defining both technical requirements and organizational needs for a structured management of procedures and operation, as will be shown in chapter 5. Considerations on operational practices arise from the same process that generates the technical requirements.

### 4.1.1 Definitions

The following definitions of 'accident' and 'hazard' are used for the STPA, as explained in (53):

- **Accident:** An accident is an undesired and unplanned event that results in a loss, including a loss of human life or human injury, property damage, environmental pollution, mission loss, financial loss, etc.
- **Hazard:** A system state or set of conditions that together with a worst-case set of environmental conditions, will lead to an accident (loss)

As from the definition, depending on the application, the term 'loss' can be related to very different quantities. The choice of what has to be considered as a 'loss' sets the boundaries and goals of the analysis. The definition of hazard differs slightly but significantly from traditional ones. It implies that hazards must be identified within the system boundaries, i.e. within quantities that can be controlled. Furthermore, some

## 4. METHODS FOR ESTIMATING THE AVAILABILITY OF PARTICLE ACCELERATORS

---

worst-case conditions must exist that could potentially lead to a loss. Such conditions do not coincide in general with component failures. A failure is an event and not a system state, therefore a failure can be the cause of a hazard, but not the hazard itself. A top level definition of accidents and hazards is then independent from the technical system implementation. This is particularly useful in early design stages.

### 4.1.2 STPA steps

The iteration of the following four steps guides the STPA application (53):

1. Establish the system engineering foundation for the analysis and for the system development
2. Identify potentially unsafe control actions
3. Use the identified unsafe control actions to create safety requirements and constraints
4. Determine how each potentially hazardous control action could occur

The first step consists in identifying the system accidents and related hazards, according to the definitions given in 4.1.1. Hazards can then be translated into safety constraints and requirements. Based on these, a high-level functional control structure can be sketched and represents the base of the next STPA iterations. This last step represents the peculiarity of the STPA, as compared to other hazard analyses. The control structure serves as a useful representation of the functional behaviour of the system. In the first iteration, the control structure is normally represented by a single controller and a controlled process, with basic interactions. Each of these parts can be decomposed and further refined. Control actions and responsibilities are assigned to the newly defined components. Communication among the different parts has to be explicitly depicted.

Once the control structure has been defined, the Unsafe Control Actions (UCA) must be identified, namely the conditions under which:

1. A control action required for safety is not provided
2. An unsafe control action is provided that leads to a hazard

3. A potentially safe control action is provided too late, too early, or out of sequence
4. A safe control action is stopped too soon or applied too long (for a continuous or non-discrete control action)

The next step is thus to identify the causes of the above unsafe control actions, by looking at the control loop and its elements. This step is fundamental as it allows defining additional safety constraints and give guidelines for mitigation of hazard causes. Delays and time dependencies are important factors to be taken into account at this stage. The result of this process is usually summarized in a table, for each of the unsafe control actions. The hazard causes can be refined in this iterative process. When a suitable mitigation is identified, then the iteration can stop. The application of this top-down procedure requires significantly less resources than traditional hazard analyses in the definition of effective mitigation strategies.

## 4.2 Availability modelling

The development and application of a method for estimating the reliability and availability of a given system architecture can be useful for several reasons. Primarily, comparing different design options gives the idea of the relative worth of each design. Nevertheless, besides availability and reliability, other factors play a significant role in the choice of the architecture, as costs, complexity and maintainability. These quantities are interdependent and strictly related to reliability and availability. For example a very complex and costly architecture may lead to the desired reliability performance, but may be difficult and expensive to maintain. The the best trade-off with available resources should be found. Once the preliminary choice of the system architecture has been made, reliability predictions allow for the identification of performance bottlenecks, at the sub-system or component level, and guide the required designed improvements before the final configuration of the system is selected for production. As an example in the case of accelerators, systems might work under extreme environmental conditions. Reliability studies highlight the need of environmental control measures. Furthermore, reliability and availability could strongly depend on operational modes and maintenance practices. From the availability perspective, reliability estimates allow for advanced considerations on the maintenance strategy to be adopted, which allows

## 4. METHODS FOR ESTIMATING THE AVAILABILITY OF PARTICLE ACCELERATORS

---

in turn to minimize the downtime of the facility. The costs to be faced for redesign of a system in advanced phases of a project can be prohibitive, therefore such studies should always be developed in parallel to the system design.

### 4.2.1 Estimates of Component Failure Rates

The study of reliability and availability figures are used for describing the failure behaviour of the system and identify potential bottle neck in the system design. Experience guides through the difficult process of estimating failure rates for a very specific application as for particle accelerators. Evaluating the consequences of a failure of a component on the overall accelerator behaviour requires a deep understanding of the functionality of the system and its interactions in a complex environment. In chapter 5 an example of the application of the estimates of component failure rates and the related study of the effects on the overall accelerator performance is presented. The analysis has been carried out in Isograph (52), a commercial tool used at CERN for reliability and availability studies. Isograph offers the possibility of selecting different standards for the prediction of component failure rates, depending on the type of system. For electronic components the Reliability Prediction of Electronic Equipment (MIL-HDBK-217F) (54) or the Telcordia (55) standards can be used. For mechanical components the NWSC (Naval Surface Warfare Center (56)) is available. The MIL-HDBK-217F is taken in the following as the reference for the calculation of failure rates of electronic components. It is based on the definition of a basic failure rate which is conveniently adjusted with additional factors to account for stress levels, environmental conditions and different quality of components. Isograph allows for the specification of such relevant factors and an automatic calculation of failure rates. Manufacturer's data relative to the failure rate, resulting from accelerated lifetime tests, should nevertheless be preferred in the analysis of a system and will therefore be used, when available. For non-standardized commercial components for specific accelerator applications, failure rates and time-to-repair are deduced from experts' experience.

What is important for the scope of the present work is to derive the consequences of a failure of a single component or system on accelerator performance. It is therefore important to study the impact of different failure modes of the components, besides their rate of occurrence. Some failures could result having no effect on the accelerator and not being relevant for its performance. For electronic components, the repartition of

the calculated failure rates to the different failure modes is done according to 'Electronic Reliability Design Handbook' (MIL-HDBK-338B). The consequences of each failure mode on the accelerator are derived by defining the high-level accelerator scenarios which could result from a component failure (see 4.3).

### 4.2.2 Reliability Block Diagrams

The Reliability Block Diagrams (RBD) and Fault Trees (FT) allow estimating the reliability of complex systems, for which basic failure modes and rates are defined as described in the previous paragraph. A RBD is made of blocks and nodes connected together in parallel or series. A voting strategy can be defined for parallel cases. In FTs, the same structure can be reproduced by means of logical gates (AND, OR, etc.). In Isograph different distributions (e.g. Poisson, Weibull, Lognormal, etc.) and standards can be used while defining failure modes. The Weibull package in Isograph is capable of assigning failure distributions to historical data; these can be used to perform simulations to reproduce the system behaviour in case of failures. In the Availability Workbench (52) the blocks in a RBD can be used to model component failures, as well as other events, such as operational decisions influencing the availability of the system. Different maintenance strategies can be defined (planned, corrective, condition-based). Once all parameters for faults and repairs are defined, a simulation of the system behaviour for a given observation time can be performed. The simulation process is based on the 'open path' model. An open path is a continuous path in the structure that does not include failed components. The software checks whether open paths exist in the structure created by the user and determines if the system is still functional. Simulation results can be followed on a so-called 'simulation watch', showing the sequence of the simulated failure events and repair actions. This provides the means to check the consistency of maintenance tasks and identify errors in the RBD or FT model. Results are presented in terms of mean unavailability, number of outages and mean repair times at the system or the sub-systems level. An analysis of costs of components, spares and personnel can also be executed with this workbench. These considerations constitute a quantitative base for the analysis of the relative worth of different design options and maintenance strategies.

## 4. METHODS FOR ESTIMATING THE AVAILABILITY OF PARTICLE ACCELERATORS

---

### 4.3 Monte-Carlo approach for Availability Simulations in MATLAB

Commercial tools allow performing a wide spectrum of analyses but have difficulties to reproduce very specific aspects of accelerator operation. Part of the availability analyses presented in this thesis have been developed in MATLAB and are based on Monte Carlo models of accelerator operation. Two different approaches have been identified for the study of availability for particle accelerators. The first follows a bottom-up approach and starts from the component level aiming at evaluating of the consequences of a component failure on accelerator operation. The second is based on a top-down view of accelerator operation and availability and relates this with accelerator performance.

**Bottom-up model of accelerator availability** The bottom-up approach is particularly suited to model systems or sub-systems which are already known and for which further design options have to be investigated. It is based on the definition of the basic failure behaviour of components. The degree of detail in the description of such failure behaviour can be chosen depending on the context of the analysis. In Chapter 4 the analysis is based on a Markov-description of the failure behaviour of components. The assumption which will be made is that all the components exhibit the same failure behaviour. This might not be valid in other contexts and be conveniently changed if necessary. Markov models allow a simple description of the component functionality that is particularly suited for building a structured model of a complex system (57). The model is based on the 'open path' verification, as in Isograph, but does not focus only on the availability or unavailability of the system. It allows identifying more complex configurations of the machine, by the definition of high-level operational scenarios. A single or a combined failure of several components leads to one of such scenarios. By estimating the frequency of occurrence of each of the defined scenarios, one can infer the availability of the system and study measures to cope with the requirements, finding a suitable balance with machine safety.

The bottom-up approach for the study of system availability could be summarized in the following steps:

1. Definition of component failure behaviour.

### 4.3 Monte-Carlo approach for Availability Simulations in MATLAB

---

2. Definition of system architecture (a system is composed of several components).
3. Definition of high-level operational scenarios (at the system-level, or higher).
4. Derivation of the frequency of occurrence of each scenario through Monte Carlo simulations.
5. Estimation of system (or machine) availability.

An application of this approach relative to identification of the best architecture for the LHC quench loop will be presented in Chapter 5.

**Top-down model of accelerator availability** The top-down approach aims at quantifying the impact of relevant aspects of accelerator operation on its performance. Knowing the dependencies among the involved quantities allows obtaining realistic estimates of accelerator performance even for machines under design or for future upgrades (e.g. High-Luminosity LHC). A top-down view of accelerator operation is based on the identification of high-level machine states. A definition of such high-level states is given in 3.1. Depending on the focus of the analysis, further machine states can be considered, as commissioning and tests, maintenance, etc. Among these, performance-relevant states can be identified, i.e. those states whose duration should be optimized for improving the scientific outcome of the facility. All states have a variable duration, depending on operational parameters. Estimating the distributions of such durations, either by observations or by dedicated calculations, and the probability of occurrence of each of the states allows re-producing a realistic timeline of machine operation. As a result, the scientific outcome can be estimated based on the integrated time spent in the performance-relevant machine state.

This approach could be summarized in the following steps:

1. Definition of high-level machine states.
2. Identification of the performance-relevant machine state(s).
3. Estimation (or derivation) of the distribution of the duration of the defined machine states.

#### 4. METHODS FOR ESTIMATING THE AVAILABILITY OF PARTICLE ACCELERATORS

---

4. Estimation of occurrence of the performance-relevant machine states through Monte Carlo simulations as a function of different parameters.
5. Quantification of accelerator performance given the estimated occurrence of the performance-relevant machine states.

An application of this approach will be presented in Chapter 5 for the predictions of LHC integrated luminosity during the future runs and for the HL upgrade.

# 5

## Availability-driven Design of MPS for Particle Accelerators

Chapter 5 focuses on availability-driven design of MPS for particle accelerators. The STPA (4.1.2) is used to guide the early design phase of the MPS, deriving the functional requirements to cope with safety and availability constraints. An example relative to the derivation of availability requirements for Linac4 is given. The second part of the chapter focuses on the analysis of different architectures of interlock systems, with a particular emphasis on finding the optimal balance between machine safety and availability.

### 5.1 Derivation of Availability Requirements

The design of MPS for particle accelerators has to face the challenging task of managing the complexity and variety of systems to be protected. Mechanical and electronic systems, as well as software, are all to be taken into account in the design, together with the many dependencies and possible interactions with human beings. In industry several examples of such complex systems exist, e.g. in the automotive domain, but on a much smaller scale. Taking the LHC as an example, only the superconducting magnet system is composed of 1232 superconducting dipoles, fed by dedicated power converters and cooled by a complex cryogenic system. Mechanical parts of the rotating machinery of cryogenic cold compressors, converter currents and magnet voltages are only some of the quantities to be consistently monitored and recorded. Common hazard analysis

## 5. AVAILABILITY-DRIVEN DESIGN OF MPS FOR PARTICLE ACCELERATORS

---

techniques are not suitable to deal with large system complexities, as required for the design of MPS. In the past the design of MPS has been based mainly on experts' experience with previous accelerators, not following a rigorous approach. The top-down approach used by STPA is conceptually suited for MPS design, as it allows a structured process, accounting for the dependencies among all relevant MPS actors. In the following paragraphs an example of the application of STPA to the design of MPS for particle accelerators is given, taking Linac4 as a case study.

### 5.1.1 Linac4 Layout and Parameters

Linac4 is the linear accelerator currently under construction and commissioning at CERN that will provide proton beams to the injector chain as of 2019. Linac4 will accelerate  $H^-$  ions up to an energy of 160 MeV (Fig. 5.1) for injection into the Proton Synchrotron Booster (PSB). The  $H^-$  beam is produced by a RF Source, with an output energy of 45 keV. A Low-Energy Beam Transfer (LEBT, 45 keV) houses a pre-chopper, transports and matches the beam to a Radio Frequency Quadrupole (RFQ) (58). The RFQ bunches and accelerates the beam up to 3 MeV. A Medium-Energy Beam Transfer (MEBT, 3 MeV) houses a chopper and matches the beam with the subsequent accelerating structures. For normal operation the pre-chopper is used to define the beam pulse length and the chopper is used to create the correct beam structure to reduce losses at injection in the Proton Synchrotron Booster (PSB). In case of faults requiring beam interruption, the choppers allow stopping the full beam at low energy (45 keV or 3 MeV). Three accelerating structures (DTL, CCDTL and PIMS) allow reaching the output energy of 160 MeV (59) (60) (61). A beam dump is placed at the end of the linac to absorb the beam, if required by machine operation (62). A series of three bending magnets can instead deflect the beam towards the transfer lines. These guide the  $H^-$  beam to the injection region in the PSB, where a stripping foil allows obtaining protons from  $H^-$  ions (24). Protons accelerated in the PSB can then be sent to different destinations. The ISOLDE Radioactive Ion Beam facility is the only user experiment connected to the PSB. The beam can alternatively be sent to an emittance measurement line or to the PS.

By 2019 Linac4 will have to meet strict requirements in terms of availability to ensure continuous beam delivery to the CERN complex, possibly reaching the performance of Linac2 operation (98 % availability). As opposed to Linac2, Linac4 will be

## 5.1 Derivation of Availability Requirements

---

equipped with a dedicated Beam Interlock System (BIS) to mitigate the consequences of beam losses on accelerator equipment.

**Figure 5.1:** Linac4 layout.

The studies related to Linac4 were developed to guide the definition of the functional specifications of the Linac4 BIS. The first step of the studies was to verify that the functional specifications would meet all the requirements arising from the application of the STPA procedure. In the following paragraphs a description of the Linac4 BIS architecture will be given, based on the outcomes of the STPA applied to Linac4.

### 5.1.2 Linac4 STPA

The first step of the STPA is to identify the set of accidents that may affect the system (see 4.1.2). Four high-level accidents (A1-A4) were identified for the case of Linac4.

- A1: Lack of beam for other accelerators
- A2: Damage to the accelerator equipment
- A3: Injuries to staff members
- A4: Release of radioactive material in the environment

System hazards (H1-H4) are then identified and correlated with each accident scenario. The goal of this analysis is the design of a MPS for Linac4. As the responsibility of MPS is only the protection of the machine and its equipment, A3 and A4 will not be further investigated, though some correlations exist with A1 and A2 and will be taken into account when necessary.

- H1: Accelerator equipment is not ready for operation [A1, A2]
- H2: The beam is lost before reaching the transfer line [A1, A2]

## 5. AVAILABILITY-DRIVEN DESIGN OF MPS FOR PARTICLE ACCELERATORS

---

- H3: The beam is stopped before reaching the transfer line when it is not necessary [A1]
- H4: The beam doesn't have the required quality for the injector chain [A1]

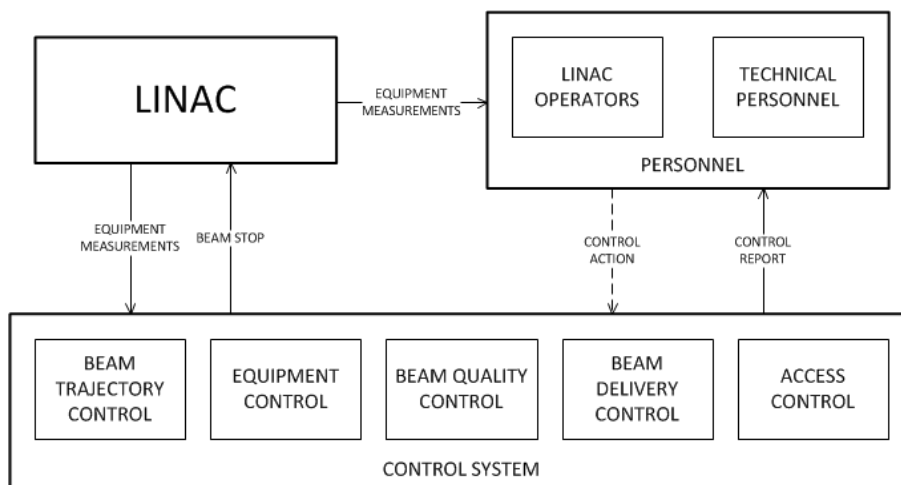

The translation of system hazards to high-level requirements (R1-R4) for the control structure is straightforward:

- R1: Accelerator equipment must be operational [H1]
- R2: The beam must not be lost before reaching the transfer line [H2]
- R3: The beam must not be stopped when it is not necessary [H3]
- R4: The beam must have the required quality for the injector chain [H4]

Given these constraints (R1-R4), a preliminary control structure can be sketched for Linac4 (Fig. 5.2). From this structure the functional behaviour of the control system can easily be deduced. The Linac has to provide feedback on its status through suitable sensors. The resulting information has to be propagated to both personnel working on the Linac and to the control system. The personnel can take actions influencing the behaviour of the machine via the control system. At the same time, the control system should have the possibility to act automatically upon the detection of particular machine states requiring an intervention on a reduced time scale. The control system is composed of sub-systems, each with a specific functionality derived from requirements R1-R4. 'Equipment Control' verifies the correct behaviour of all Linac hardware systems. The 'Beam Trajectory Control' checks that the beam is following the designed trajectory and is not lost under dangerous circumstances. The 'Beam Quality Control' allows establishing if the requirements imposed by the following accelerators in terms of beam performance are met. The 'Beam Delivery Control' ensures optimized delivery of the beam to different beam destinations. Furthermore, a link to personnel protection is explicitly foreseen in the control structure ('Access control').

The described high-level control structure can then be refined to account for more detailed interactions among the identified components (Fig. 5.3). The Linac is now including hardware subsystems and instrumentation for feedback to personnel and control system. The functional dependencies and responsibilities of each block can be deduced

## 5.1 Derivation of Availability Requirements

**Figure 5.2:** High-Level control structure: The figure shows the basic control structure derived from requirements R1-R5.

by actions/feedback indicated by arrows in the structure. The main control action of the control system is the 'Beam Stop', that allows interrupting the beam transmission if required by any of the subsystems connected (directly or indirectly) to the Equipment Control.

Based on Fig. 5.3 and according to what described in 4.1.2, the next step is to study the potentially Unsafe Control Actions (UCAs). The analysis focuses on the main control action of the control system, the 'Beam Stop'. A beam stop can either be initiated by an operator or automatically if a sensor or instrumentation detects a non-nominal operating condition. The information of a beam stop request has to be propagated from the source requesting it to the actuators (i.e. the choppers). The process variables related to the control action 'Beam Stop' have been identified and are reported in Table 5.1. These are the relevant factors to be taken into account when trying to identify the UCAs.

Combining the possible configurations of the defined process variables brings to the definition of the possible operational scenarios in which a beam stop is executed (63). As a result it can be evaluated whether performing or not the control action can result in a hazard. This leads eventually to the identification of unsafe control actions (UCAs, Table 5.2).

The following unsafe control actions were identified through the described procedure:

## 5. AVAILABILITY-DRIVEN DESIGN OF MPS FOR PARTICLE ACCELERATORS

**Figure 5.3:** High-Level control structure: The figure shows a refined control structure derived from requirements R1-R5.

## 5.1 Derivation of Availability Requirements

---

Process Variable	Possible Values	Notes
Trigger of beam stop request	Manual Automatic None	A beam stop can be requested by an operator with a manual command ('Manual'). A beam stop can be automatically initiated by a sensor in case non-nominal operating conditions are detected ('Automatic'). A beam stop cannot be initiated at all ('None').
Validity of beam stop request	Valid Invalid	A beam stop can be necessary, following the detection of non-nominal operating conditions ('Valid'), or not necessary in case of operator mistake or wrong sensor detection ('Invalid')
Beam Quality	Acceptable Not Acceptable	The beam must have a minimum quality for the different destinations ('Acceptable'). The possibility exists that the beam quality is not sufficient ('Not Acceptable').
Actuator status	Ready Not ready	The actuator must be operational for a correct execution of a beam stop ('Ready'). In case the actuator is not operational, the beam stop cannot be executed ('Not ready').
Status of beam destinations	Available Not Available	Beam destinations must be available to receive beam from the Linac during nominal operation ('Available'). The possibility exists that no destination is available ('Not Available')
Accelerator Mode	Access Beam Operation	The accelerator is normally operated with beam ('Beam Operation'), but maintenance with direct interventions on accelerator equipment is executed during predefined time periods or following equipment failures ('Access').

**Table 5.1:** List of relevant process variables for the execution of a beam stop.

## 5. AVAILABILITY-DRIVEN DESIGN OF MPS FOR PARTICLE ACCELERATORS

CA provided in hazardous state: Beam stop executed									
ID	Trigger	Validity	Beam Quality	Actuator	Other Accelerators	Mode	Hazardous?	Hazard	UCA
1.1	-	Invalid	-	Ready	Available	-	Unnecessary stop of beam delivery to the destinations. Loss of beam availability.	H3	UCA1

CA provided in hazardous state: Beam stop not executed									
ID	Trigger	Validity	Beam Quality	Actuator	Other Accelerator	Mode	Hazardous?	Hazard	UCA
1.2	-	Valid	-	Not ready	-	Beam Operation	The beam is not stopped and can cause damage to the accelerator equipment	H2	UCA2
1.3	-	Valid	-	Not ready	-	Access	The beam is not stopped and personnel can be exposed to radiation	(H)	UCA3
1.4	None	Valid	-	Ready	-	-	The beam is not stopped and can cause damage to the accelerator equipment	H2	UCA4

**Table 5.2:** Identification of UCAs related to the control action ‘Beam Stop’.

**UCA1** The beam is stopped when it is not necessary (automatically or by an operator)

**UCA2** The beam is not stopped in a detected emergency situation (automatically or by an operator) due to the unavailability of an actuator

**UCA3** The beam is not stopped while personnel has access to the linac

**UCA4** The beam is not stopped following the missed detection of an undesirable accelerator configuration

**UCA5** The beam is not stopped when the beam quality is not sufficient for the injectors

Given the above unsafe control actions, the next step of the STPA analysis consists in the identification of causal scenarios of each of the unsafe control actions. As the focus of the analysis is on availability of the control system, the details relative to UCA1 are reported in Tables 5.3 and 5.4.

Refined requirements are found by defining the causal factors leading to the UCA. These requirements can directly be allocated to new components in the structure or trigger further design studies. It is interesting to notice the different nature of the

## 5.1 Derivation of Availability Requirements

UCA: a beam stop is executed when it is not necessary			
Scenario	Associated Causal Factors	Notes	Requirements
[Control input or external information wrong or missing]  Operators trigger an unnecessary beam stop	Operators accidentally act on the physical device connected to the controller	The emergency button in the control room is accidentally pushed	Protect the physical device from accidental contact
	Operators misinterpret feedback from instrumentation and trigger the beam stop	The operator misinterprets a signal (e.g. judging it as a relevant deviation from nominal operation) and decides to stop the beam for safety reasons	Train operators to use softwares and processes running in the control room
	Operators perform an action that triggers a dangerous situation and thus a beam stop	The operator tries to compensate a beam or hardware setting but this leads to a dangerous state that requires a beam stop	Train operators to use softwares and processes running in the control room
	Technical personnel tries to access the linac while it is working, causing a beam stop	Technical personnel is unaware that the machine is running and tries to access it	Require authorization from the control room for machine access
[Sensor - Inadequate or missing feedback]  The sensor feedback is wrong and automatically triggers a beam stop	Sensor is faulty and causes a beam stop	A sensor signals its faulty state and determines a beam stop, even if no direct machine harm exists	A dedicated reliability analysis can assess what is the ideal number and type of sensors to be used to minimize the occurrence of false or missed detections
	Spurious trigger of a sensor causing a beam stop	A sensor signals a hazardous operating condition due to a spurious failure (e.g. radiation-induced)	Consider adding redundancy.  When possible, locate sensors and instrumentation far from radiation-exposed areas
	Operating conditions have changed and the sensor needs a re-initialization	A sensor is operated with new boundary conditions but old settings and triggers a beam stop, even if no direct machine harm exists	Introduce pre-operational checks at predefined times (e.g. after every maintenance period)
[Sensor - Inadequate or missing feedback]  The sensor doesn't provide feedback over a certain time and a beam stop is triggered	Communication between sensor and control system is lost	A sensor doesn't provide a feedback on its status over a predefined time window and triggers a beam stop for safety reasons	If redundancy exists, define a procedure or hierarchical organization to decide whether continuing operation in degraded monitoring conditions is acceptable or not
	The sensor feedback is stuck on a fixed value over a certain time	A sensor sends to the controller a signal stuck at the same value over a predefined time window and triggers a beam stop	If redundancy exists, define a procedure or hierarchical organization to decide whether continuing operation in degraded monitoring conditions is acceptable or not
	Communication between a given monitored device and the sensor is lost	A sensor loses communication with the reference monitored device or quantity and triggers a beam stop	A dedicated reliability analysis can assess what is the ideal number and type of sensors to be used to minimize the occurrence of false or missed detections

**Table 5.3:** Example of STPA-driven derivation of requirements: analysis of causal factors leading to UCA1.

## 5. AVAILABILITY-DRIVEN DESIGN OF MPS FOR PARTICLE ACCELERATORS

UCA: a beam stop is executed when it is not necessary			
Scenario	Associated Causal Factors	Notes	Requirements
<p>[Controlled process - unidentified or out-of- range disturbance]</p> <p>The operating conditions have a sudden change due to external disturbances and cause a beam stop, even if nominal conditions would be automatically recovered</p>	Electrical disturbances affecting magnet power converters	Sudden electrical disturbances may affect the beam trajectory and result in a beam stop, even if the effect would not be observed or observed for a short time (not leading to a hazardous situation)	Design filters and logics to prevent beam stops triggered by electrical disturbances
	Electrical disturbances affecting RF powering	Sudden electrical disturbances may affect the beam quality and result in a beam stop, even if the effect would not be observed or observed for a short time (not leading to a hazardous situation)	Design filters and logics to prevent beam stops triggered by electrical disturbances
<p>[Controller - Process Model inconsistent, incomplete, or incorrect]</p> <p>The controller, based on the feedback from the sensors, triggers a beam stop when it is not needed</p>	Wrong settings are used for the beam stop trigger	The controller algorithm is fed with wrong inputs for the computation of the controller action to be taken (e.g. wrong choice of beam loss thresholds)	Perform dedicate campaign for computation of relevant parameters for the controller algorithm
	Wrong settings are loaded in the controller	Wrong settings are manually entered in the controller	Deploy a role-based system for loading the settings, such that only people with access rights can modify critical parameters
<p>[Controller - Inadequate Control Algorithm]</p> <p>The controller spuriously triggers a beam stop</p>	A beam stop is triggered following a random hardware failure of the controller	The controller hardware generates a beam stop trigger even if the control algorithm doesn't detect a hazardous operating condition (e.g. due to radiation-induced effects)	A dedicated reliability analysis can assess what are the critical components of the controller and determine if redundancy should be added to minimize the occurrence of such effects.
	Electrical disturbances	Sudden electrical disturbances may result in a signal that can be interpreted as a beam stop trigger by the actuator	A dedicated reliability analysis can assess what are the critical components of the controller and determine if redundancy should be added to minimize the occurrence of such effects.
<p>[Controller - Inadequate Control Algorithm]</p> <p>The controller cannot find a valid beam destination and triggers a beam stop</p>	Missing logic to calculate valid beam destinations	The unavailability of the scheduled destination is not handled correctly by the control system	A dedicated system managing dynamically the calculation of beam destinations should be foreseen
<p>[Actuator - Inadequate Operation]</p> <p>The actuator spuriously triggers a beam stop</p>	A beam stop is triggered following a random hardware failure of the actuator	The actuator executes a beam stop, but this is not initiated by the control system. A hardware fault, e.g. of the actuator powering can lead to a spurious beam stop.	The occurrence of hardware failures of the actuator must be minimized.

Table 5.4: Analysis of causal factors leading to UCA1.

## 5.2 Definition of Interlock System Architectures

---

requirements emerging from the application of the STPA. Requirements range from technical (e.g. the need of redundant monitoring of particular failures) to organizational and managerial (e.g. the need for dedicated training of linac operators), to procedural (e.g. the requirement of Role-Based Access Control - RBAC - for the approval of particular actions on the machine).

From the MPS technical design point of view, further studies are needed to identify the ideal configuration of sensors used to detect accelerator failures. This aspect requires accurate analyses to ensure that the required level of safety is met without compromising availability. In 5.2 dedicated studies on redundant architectures for failure detection and interface with the interlock system are presented.

Every change made to the control structure shown in Fig. 5.3 following the definition of UCA causal factors requires a further iteration of the STPA procedure. This ensures that new changes to the structure do not introduce additional sources of potential unsafety in the system.

## 5.2 Definition of Interlock System Architectures

In 3.3 the relationship between MPS and availability has been described. MPS for particle accelerators relies on electronic systems, called interlock systems, to cope with hazards arising from accelerator operation. The basic functionality of an interlock system is shown in Fig. 5.4. A set of sensors allows monitoring relevant quantities of accelerator equipment and beam-related parameters. These constantly verify that parameters are within acceptable operating ranges. The feedback provided by sensors is normally not directly fed into the interlock system. This is done to limit the complexity of the logic implemented in the interlock system. Local electronics is designed to process data from sensors and identify the occurrence of a dangerous machine configuration. The interlock system is in charge of gathering the outputs of local electronics from different sensors (called ‘users’) and determine whether an action has to be taken to stop accelerator operation. The interlock system communicates with the actuators in order to inhibit operation, if required.

Depending on the machine layout and components, different actuators and strategies to inhibit operation are implemented (see 3.3.1, 3.3.2). In case the action taken by the actuators is to inhibit beam operation, i.e. by triggering a beam dump or a beam

## 5. AVAILABILITY-DRIVEN DESIGN OF MPS FOR PARTICLE ACCELERATORS

---

**Figure 5.4:** Schematic view of the functionality of an interlock system for particle accelerators.

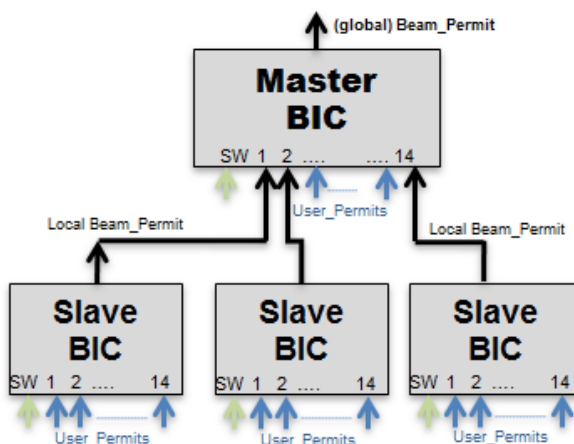

stop, the interlock system is called Beam Interlock System (BIS). In the following a description of different architectures of interlock systems is given, with a particular emphasis on addressing the problem of finding the optimal balance between safety and availability for the design of future interlock systems.

### 5.2.1 Linac4 Beam Interlock System

The architecture and functionality of the Linac4 BIS are discussed in this paragraph. The Linac4 BIS is based on the LHC-type beam interlock system, namely it uses a combination of hardware interlocks (the BIS), and software interlocks (the Software Interlock System, SIS) (64), to protect accelerator equipment from beam-induced damage (65). Local equipment protection (e.g. magnet overheating due to a cooling failure) is outside the BIS and SIS, as well as personnel protection. In the case of Linac4, a third hardware system, the so-called External Conditions (EC), is interfaced with the BIS to ensure optimized beam delivery to the different beam destinations. A set of parameters depending on the beam destination are interpreted by the timing system to determine the cycles to be executed. In case a destination is not available, another cycle can be selected and executed instead. This additional system allows maximising the Availability for Physics, avoiding the limitation imposed by the unavailability of an individual destination.

The hardware of the Linac4 BIS is almost entirely inherited from the LHC BIS. The LHC BIS was designed in 2006 for very high dependability and is currently in use also at the SPS. Dependability requirements were expressed in terms of tolerable number of unsafe events (i.e. potentially leading to catastrophic damage of equipment) per year and false dumps per year (31). The LHC BIS was designed with the constraint

## 5.2 Definition of Interlock System Architectures

**Figure 5.5:** The Tree-Architecture of the BIS.

of not causing more than  $0.5 \pm 0.4$  false dumps per year. The beam power of Linac4 will be orders of magnitude lower than that of the LHC and thus its damage potential. The focus of the interlock system should therefore be headed towards minimizing the number of false beam stops over the run, as all the CERN accelerator complex will be fed by Linac4 after its deployment, foreseen in 2019. Nevertheless the damage potential of low-energy beams must not be underestimated and so the protection requirements. The energy deposition for low-energy beams is confined in a very limited volume and can be sufficient to cause local melting of delicate accelerator equipment. An example of beam-induced damage by a 3 MeV beam is given in A.1.

With respect to the LHC BIS, the architecture of the Linac4 BIS had to be modified to cope with the different requirements of a linear accelerator.

The architecture features the use of the tree-topology, based on the daisy-chain configuration of controllers (Fig.5.5). In this configuration a set of controllers ('Slaves') are used as inputs of another set of controllers ('Masters'). Master controllers are connected to the actuators, providing the 'Global Beam Permit' signal. They are therefore in charge of triggering a protection action based on the status of their inputs. Such inputs may come from direct equipment feedback ('User Permit') or from the output of slave controller ('Local Beam Permit'). In the case of slaves, inputs are only 'user permits' and a logic AND function of the inputs is calculated to produce the local beam permit. This means that all the inputs must be 'OK' (or '1') to have the permit.

## 5. AVAILABILITY-DRIVEN DESIGN OF MPS FOR PARTICLE ACCELERATORS

---

For master controllers the logic to give the beam permit can be more complex and is defined by a truth table. Every row in a truth table represents a valid configuration of the inputs to give a valid global beam permit ('1'). The status "x" ('don't care') implies that the condition associated to the given input is NOT RELEVANT for giving the beam permit.

Each controller has a maximum of 15 inputs, one of which is always dedicated to the SIS. The SIS is used to monitor slow-changing parameters or to implement complex logic, which would be difficult to reproduce via hardware. It is used as a second layer of protection, as critical processes are always monitored by hardware interlocks. The SIS is also exploited to implement temporary interlocks for particular phases of the accelerator lifetime (e.g. commissioning), when operational flexibility for correct machine tuning must be ensured (66).

A schematic overview of the Linac4 BIS architecture is shown in Fig. 5.6. The BIS is composed of two master controllers, the MASTER SOURCE RF and the MASTER CHOPPERS (65). The first is responsible to trigger the RF controller of the ion source in case a danger is detected in the first part of the linac (i.e. before the DTL). For redundancy the pre-chopper is also triggered by the same signal. All inputs of this controller are user permits, i.e. no slave controller is providing an input.

The MASTER CHOPPERS is in charge of triggering a beam stop in case a failure is detected in the second part of the Linac (i.e. downstream the DTL), in the transfer lines to the different beam destinations or in the dump line. The injection in the PS Booster is also monitored, to eventually inhibit beam transmission in case no beam destinations are available. Each of the mentioned sections monitored by the BIS are indicated as 'interlock zones' and are served by a dedicated slave controller. A total of 7 slave controllers provide inputs to the MASTER CHOPPERS. The beam stop in this case is executed by triggering both the pre-chopper and chopper. As an additional measure to control the beam in case of a failure, also the RF system of the PSB is switched-off. The truth tables of the two master controllers are shown in Fig. 5.7 and 5.8 for exemplification and those of the slave devices in A.2.

### 5.2.2 ESS Beam Interlock System

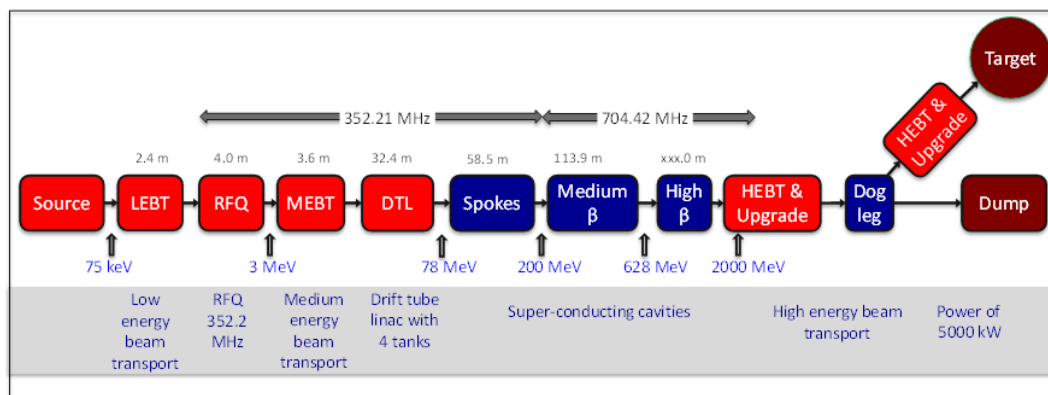

#### 5.2.2.1 ESS Layout and Parameters

ESS is an accelerator-driven facility for neutron experiments (8). It includes a 600 m long Linear accelerator and a transfer line connecting a high-power proton beam (average current: 62 mA, pulse length: 2.86 ms, repetition rate: 14 Hz) to a rotating, helium cooled 6 T tungsten target. Neutrons are produced via a spallation process by the interaction of the proton beam with the target and are then guided to user experiments. ESS protection systems should not only cover the accelerator section, preventing beam-induced damage to equipment located in the tunnel, but also the target and neutron experiments. The high power proton beam can cause severe damage of expensive equipment, therefore a dependable BIS is one of the fundamental elements for the operation of this facility.

The ESS accelerator layout is shown in Fig. 5.9. It is composed of a warm low-energy section and a superconducting section. Protons are produced by a magnetron source. The warm section is then composed of a Low-energy beam transfer, a Radio Frequency Quadrupole (RFQ), a Medium energy beam transfer and a set of normal conducting cavities (DTL). In the LEBT the beam is focused and matched to the RFQ, where is then bunched and accelerated up to 3 MeV. The MEBT ensures focusing and matching to the Drift Tube Linac (DTL) where the beam is accelerated up to 78 MeV.

## 5.2 Definition of Interlock System Architectures

**Figure 5.9:** Schematic view of the ESS Linac and transfer lines to the dump and target.

The LEBT and MEBT also house the choppers, which define the beam pulse length. The superconducting part includes the so-called spokes (67), Medium (68) and High-Beta (69) cavities, that allow reaching the nominal output energy of 2 GeV. At the end of the Linac the beam can then be sent to a dump or to the target via a dedicated transfer line. If the target is chosen as beam destination, a series of bending magnets guides the beam to the rastering system section and then to the target. The latter is subdivided in segments. The rastering system (70) deflects consecutive bunches in a pulse to different points in a segment. This allows in combination with the 14 Hz rotation of the target to significantly reduce the frequency of beam impacts in the same location and spread the peak power density over a larger area than without using the rastering system.

The ESS layout in the warm-section is very similar to the Linac4 layout. The difference between these two accelerators can be mainly addressed to the higher beam power and the presence of superconducting cavities at ESS. These two factors have a large impact on MPS. Damage potential to the accelerator equipment is drastically increased for ESS, as well as downtime associated to each recovery after a failure. In the following, the protection strategy and the definition of the ESS BIS architecture will be presented, based on the experience with Linac4 MPS. Considerations on relevant operational aspects for the definition of the BIS architecture will also be highlighted.

## 5. AVAILABILITY-DRIVEN DESIGN OF MPS FOR PARTICLE ACCELERATORS

---

### 5.2.2.2 Interlocking Strategy

A suitable interlocking strategy is needed to cope with all relevant failure scenarios that might occur during accelerator operation. Despite the similarities with Linac4, which suggest adopting a similar BIS architecture for ESS, some careful considerations on the protection of sensitive equipment due to the increased beam power are needed. The beam power in the low-energy section of the ESS Linac amounts to some kW, assuming nominal beam parameters. This implies that the damage level of materials (e.g. copper) is already reached in the warm Linac. A full beam pulse impacting on accelerator equipment can never be tolerated. Three actuators, namely the RF magnetron of the proton source and the LEPT and MEPT choppers, are used to stop the beam production in case a failure is detected. This allows limiting the amount of beam losses potentially caused by the failure. Redundancy in the actuation of the protection function is needed to ensure that a beam stop is performed even in case of a failure of one of the actuators. The actuators have different reaction times. If the RF magnetron of the proton source is switched-off, beam production is stopped within 100  $\mu$ s. The LEPT chopper can be switched ON (i.e. deflecting the beam out of the nominal trajectory) within 300 ns. The MEPT chopper can be switched ON within 10 ns. For fast reaction times one has to rely on the choppers. These are capable of deflecting the beam towards dedicated absorbers in a significantly reduced time compared to the source de-activation. Nevertheless given the high beam power, absorbers are not capable of withstanding a full beam pulse even at low energy, therefore the source always needs to be switched off ultimately. A fourth option to inhibit the beam transmission to the high-energy section of the Linac4 is represented by the trigger of a power shutdown of the RFQ, but is not assumed here as the baseline.

Fast reaction times of the actuators are necessary to limit the amount of beam which is transmitted to a given destination while beam operations is being inhibited. It has been quantified that the time allowed until beam is being switched-off is in the order of 10  $\mu$ s (71). Table 5.5 summarizes the contributions to the overall reaction time. Assuming that BLMs are capable of detecting a fast beam loss in about 2  $\mu$ s, the information has to be propagated to the BIS, after being validated. This takes less than 1  $\mu$ s, considering a negligible distance between the BLMs hardware and the BIS hardware. The BIS receives the change of beam permit and issues a beam stop request.

## 5.2 Definition of Interlock System Architectures

---

Event	Required Time [ $\mu\text{s}$ ]
Sensor detects a failure at position X (e.g. BLMs)	2
Local electronics informs the BIS	$<1$
BIS issues a beam stop request	$<1$
BIS request transmitted to the actuator	2 - 3
Actuator stops the beam (e.g. MEBT chopper)	$<1$
Beam stops at position X (e.g. at the end of the Linac)	4
	10

**Table 5.5:** ESS MPS minimum reaction time.

The latter is transmitted to the actuators. Considering a distance of 600 m (worst case) from the location of the beam loss to the actuator, 2-3  $\mu\text{s}$  should be accounted. The reaction time of the actuator varies as explained. The time before the beam stops at the location when losses occur should consider the beam which is already in the Linac and that cannot be stopped (4  $\mu\text{s}$  for 600 m), related to the time of flight of the protons. In total 10  $\mu\text{s}$  are found.

The logic of the BIS has to cope with operational constraints. The priority is to preserve availability by assuring reproducible operation and fast maintenance. A modular design including six different destinations has been studied for the ESS BIS:

1. Beam up to the Faraday Cup of the LEBT.
2. Beam up to the Faraday Cup downstream the RFQ.
3. Beam up to the Faraday Cup between DTL and spokes cavities.
4. Beam up to the Faraday Cup of the Medium Beta section.
5. Beam to the tuning beam dump.
6. Beam to the target.

The availability of each destination depends only on the status of the previous destinations and is independent on the status of the following. The only exception regards the beam dump and the target (5 and 6), which are both valid destinations when the other is not available, respectively. Systems as faraday-cups and the dump

## 5. AVAILABILITY-DRIVEN DESIGN OF MPS FOR PARTICLE ACCELERATORS

---

are designed in order to accept only beams with given parameters, below nominal values. A full power beam can only be sent to the target. The definition of different destinations has thus to be complemented with the definition of operational modes. Each operational mode is identified by limits set on acceptable beam parameters. If feedback from beam instrumentation measures beam parameters outside the tolerances of the given operational mode, then beam operation has to be stopped. The definition of beam destinations and beam parameters combined into specific operational modes is particularly useful for machine commissioning and tests. On one hand it allows safely changing beam parameters and machine settings, on the other hand it allows a ‘modular’ operation of different accelerator sections, without requiring a change of the interlock logic. This is a huge advantage for maintenance of the BIS and of other accelerator equipment.

In the following, a description of the interlocking strategy for each of the ESS sections shown in Fig. 5.9 is given. Monitored parameters to be connected to the BIS are highlighted. As explained in 5.4, it is assumed that a combination of interlock signals for a given set of sensors is executed locally and that only few signals are sent for feedback to the BIS. This ensures limiting the complexity of a highly critical system, as desirable.

**Proton Source** The proton source should provide to the BIS a signal representing its readiness for operation. This combines the status of the water cooling circuit, a measurement of the water conductivity, the status of power supplies and feedback from vacuum valves position and magnetic field measurements.

**Low Energy Beam Transport (LEBT)** The LEBT houses two solenoids and two steering magnets (one per solenoid) for beam focusing and trajectory corrections. An iris is used to control the beam current by a variable aperture. The LEBT chopper is one of the actuators of the BIS. Both its powering and water cooling should be monitored and connected to the BIS. A Faraday Cup and two Allison scanners (horizontal and vertical) allow measurements of beam characteristics. Even at low energy (75 keV), the long pulse length (6 ms including the time for the pulse stabilization) together with the high repetition rate (14 Hz) and high beam current (up to 100 mA) the beam damage potential is significant. In case of a solenoid failure or a wrong deflection by the steering

## 5.2 Definition of Interlock System Architectures

---

magnets for example, the beam could be lost in the LEBT. The pulse energy is 45 J and the power 630 W. This is sufficient to damage delicate equipment. This implies that an interlock for the currents of both solenoids and steering magnets is required. Failure modes associated to the powering of steering magnets can lead to faster beam losses than in the case of solenoids, with more focused beams. The Allison scanners and the faraday cup are movable devices that are inserted in the beam for measurements. It is assumed that only one device can move into the beam at a time. End-switches will monitor the position of such devices and should provide an interlock in case of wrong positions, according to the operational mode.

The iris used to adjust the beam current has a delicate and complex design. It is composed of eight movable blades (each a few mm thick), possibly requiring water-cooling. If the water-cooling stops, beam operation needs to be stopped to prevent damage to the iris.

**Radio Frequency Quadrupole (RFQ)** The RFQ requires interlocking, as other RF components, relative to the status of the powering system (i.e. power supply, cooling).

**Medium Energy Beam Transport (MEBT)** The MEBT houses three buncher cavities and quadrupole magnets for correct matching of the beam to the accelerating cavities. Compact collimators (6 cm) are used to limit the transverse beam tails. Wire scanners allow measuring both the horizontal and vertical profiles. The MEBT chopper is the last actuator of the BIS.

The status of the buncher cavities powering should be monitored. Only operation without the second buncher cavity can be accepted, reducing the output power up to 50 % of the nominal. The beam has to be stopped in case of a failure of a buncher cavity, therefore an interlock is foreseen. Similarly to the case of the LEBT, both cooling and powering of quadrupoles and chopper in the MEBT should be interlocked. The chopper absorber in the MEBT cannot withstand a full pulse at nominal current and is only capable of absorbing a pulse length up to 0.5 ms. An interlock monitoring the secondary emission signal from the absorber could be used to monitor the maximum allowed energy deposition in the device. If the signal duration exceeds a predefined time

## 5. AVAILABILITY-DRIVEN DESIGN OF MPS FOR PARTICLE ACCELERATORS

---

window, a signal will be sent to the BIS to stop the beam at lower energy (secondary emission time window interlock).

The carbon wire scanners are activated by a stepping motor and are inserted at an angle of 45 deg. The wire insertion should only be allowed in certain operational modes, when the current is sufficiently low to preserve the wire integrity. Concerning the movable collimators, the jaw position and temperature should be monitored. An application of the secondary emission time window interlock could also be foreseen in this case.

**Drift Tube Linac (DTL)** The DTL is composed of five tanks, housing cavities, permanent quadrupole magnets, steering magnets and beam instrumentation. Each tank is supplied with RF power by one RF cell. Each RF cell should provide a signal representing its status to the BIS. Furthermore steering magnets in the DTL have a small inductance that may lead to fast beam deflections in case of powering failures. The powering of these devices has therefore to be interlocked. BLMs can be used to detect beam losses in the last DTL tanks, whereas for the first DTL tanks the beam energy is too small to be detected (41). Diamond BLMs located inside the drift tubes where the steering magnets are placed could potentially cope with fast loss scenarios. The Faraday Cup after the DTL is one of the foreseen intermediate beam destinations, to be used during commissioning and tuning of the accelerator. The device will be designed to accept the full beam current for 100 s, when operating at 1 Hz. Monitoring of the position of the Faraday Cup is required.

### Superconducting Linac

**RF System** The superconducting Linac is composed of spokes, medium beta and high beta cavities. Each RF cell includes a modulator, klystrons or tetrodes, a Low-Level RF (LLRF) system, a circulator, a local controller and a local protection unit (so-called local RF interlock system). The latter is responsible for monitoring both fast RF failures (e.g. arcing) and slow failures (e.g. due to cooling). This represents the interface to the BIS. The number of RF signals to be routed to the BIS has been estimated to be in the order of 125, i.e. one per RF cell. From experience it is expected that RF trips will give the highest contribution to the number of beam stops. To achieve high availability,

## 5.2 Definition of Interlock System Architectures

---

a logic to cope with intermittent faults could be implemented for further performance optimization, but is foreseen only for a later stage. In this case beam pulses would be inhibited only when necessary. High availability can be also achieved by operating the accelerator in ‘degraded mode’, i.e. without one or more faulty cavities. Following suitable de-tuning of the faulty elements and a consequent rearrangement of the cavity settings, operation with reduced beam power is possible (see 3.2).

**Beam Loss Monitors** About 250 BLMs will be installed for ESS. These will monitor beam losses by comparing measured signals with predefined thresholds. Both threshold comparison and signal aggregation from different BLMs will be done in the local electronics to reduce number of cables to the BIS.

**Beam Current Monitors** Beam Current Monitors (BCMs) measure the beam current at a given location. The difference between beam current measurements at two locations can be used to infer the amount of beam losses, by comparing it with predefined damage or quench thresholds. BCMs allow for a redundant beam loss measurement to be connected to the BIS. The total number of BCMs in the ESS Linac amounts to 21 (considering also the warm Linac), resulting in about five signals to the BIS. BCMs are also fundamental to determine if the requested beam mode, specified in terms of pulse length, beam current and repetition rate, is consistent with machine protection settings.

**Vacuum** Each section of the accelerator should provide a signal summarizing vacuum conditions and the status of vacuum equipment. In particular the status of vacuum pumps and valves should be interlocked. Manual valves should provide a remote position readout measurement.

**Cryo-modules** A total of 43 cryo-modules housing 146 superconducting cavities constitute the cold Linac. It is assumed that local fast protection of the RF system will be designed to react upon the measurement of abnormal cryogenic conditions. This is also interfaced with the BIS and will trigger a beam stop. In addition a slower monitoring of the global cryogenic status, gathering signals from the different cryo-modules, could be foreseen. This is particularly useful to inhibit machine start-up with non-nominal cryogenic conditions.

## 5. AVAILABILITY-DRIVEN DESIGN OF MPS FOR PARTICLE ACCELERATORS

---

**Magnets and Power supplies** Approximately 100 magnets are foreseen in the ESS design:

- Quadrupole magnets along the entire accelerator
- Steering magnets for the horizontal and vertical compensation.
- Two dipole magnets connecting the Linac output to the transfer line to the target (powered in series)
- Raster magnets (four horizontal and four vertical) to distribute the beam on the rotating target surface

Depending on the magnet type and its criticality, different powering schemes are considered. An important parameter to take into account for magnet monitoring systems is the time constant for beam trajectory changes produced for the two main failure cases, namely a trip of the power supply and the power supply providing maximum voltage. These are respectively the most common and the most serious failure scenarios. The current for each magnet circuit will be monitored using AC/DC current sensors (DCCTs). The water cooling, when present, should also be monitored by dedicated flow-meters. For slow failures, parameters can be managed by a PLC comparing the current for all circuits with nominal values. If a current of a specific circuit is outside a predefined window, the beam permit is removed for the beam interlock controllers that are relevant for the section. A similar system has been in use at CERN (72). For particularly fast failures more sophisticated monitoring of the current, with tight tolerances on current values and, eventually, on current changes over time, could be deployed.

The dogleg dipole and steering magnets are operating with a constant current and are the most critical. In case of a powering failure, the beam could be deflected towards the vacuum chamber and the surrounding equipment. The raster magnets (operating with an AC current) are also critical, as in case of failure the energy density from the beam passing through the proton beam window in front of the target can reach the damage level.

## 5.2 Definition of Interlock System Architectures

**Figure 5.10:** Master Level 1 of the ESS Beam Interlock System: inputs are in green and outputs in red.

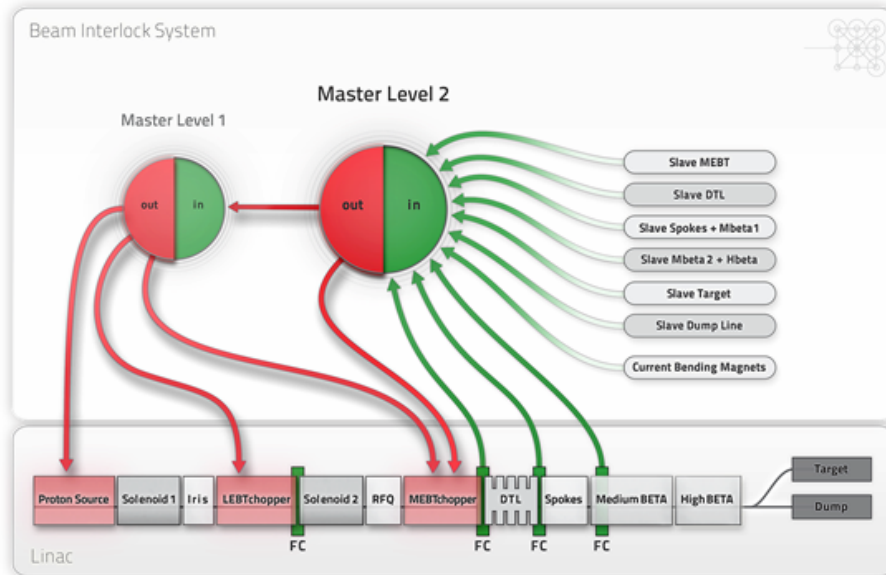

**Target** The target station will be protected by a dedicated system. This system should be interfaced with the BIS to inhibit beam transmission to the target in case of failures. The rotation of the target wheel must be synchronized to the incoming beam. Therefore the target monitoring system should provide to the BIS a signal indicating if the correct position for receiving beam is maintained. Furthermore slowly varying conditions determining if the target is ready to receive beam (e.g. temperature) should be monitored. The status of the proton beam window separating the accelerator vacuum from the helium for target cooling should be monitored as well.

### 5.2.2.3 BIS: Architecture

Given the similarities in the layout with Linac4, for the ESS BIS the tree-architecture is also chosen (see Fig. 5.5). It makes use of the daisy-chain feature, where an output of one beam interlock controller (slave) is connected to the input of another beam interlock controller (master). Based on the configuration of the inputs of master devices, beam transmission in the Linac is allowed or stopped by the actuators.

The ESS interlock architecture is composed of master and slave controllers as shown in Figs 5.10 and 5.11.

## 5. AVAILABILITY-DRIVEN DESIGN OF MPS FOR PARTICLE ACCELERATORS

**Figure 5.11:** Master Level 2 of the ESS Beam Interlock System: inputs are in green and outputs in red.

The MASTER LEVEL 1 acts on the generation of RF field in the proton source magnetron and on the high voltage of the LEBT chopper. If the conditions for beam operation are not fulfilled, the magnetron is switched OFF and the high voltage of the LEBT and MEBT chopper is switched ON. The Master level 2 verifies the availability to receive beam in the different sections of the accelerator, depending on the beam destination. Six beam destinations have been identified. The status of the elements downstream each destination is not relevant to give the beam permit. The Master level 2 acts on the high voltage of the MEBT chopper and provides an input to the Master Level 1, to always trigger the action on both the magnetron of the RF source and the LEBT chopper, also in case of a failure of the MEBT chopper. Slave devices gather relevant signals from different sections of the Linac, transfer lines and target station. A detailed overview on the list of signals for the ESS BIS can be found in B.1.

### 5.2.3 Interlock Loops for MPS

Interlock systems for machines with very demanding dependability requirements may require the design of different architectures than what described in the previous paragraphs. MPS at CERN often makes use of so-called interlock loops to implement

## 5.2 Definition of Interlock System Architectures

**Figure 5.12:** Schematic view of the LHC BIS loop.

protection functions. The basic principle is that several systems (i.e. sensors) are interfaced with the loop and can potentially interrupt the signal transmission in the loop to indicate to the actuators the occurrence of a failure. Accordingly two failure scenarios can occur: 1) not triggering the actuator(s) in case of a sensor signal and 2) triggering the actuator(s) in absence of a sensor signal. The first failure scenario interferes with machine safety and can generally be described as a missed action. The second interferes with machine availability and can be described as a spurious action. MPS dependability requirements associated to the protection function implemented by the interlock loop can be met by adding redundancy at the loop level (and/or at the sensor level) and a suitable voting strategy. For future facilities with critical MPS and dependability requirements, as e.g. ITER (73) or the FCC, the choice of a suitable interlock system architecture is a vital aspect of machine design. In the following, examples of existing interlock loops at CERN are given and studies on extended architectures based on advanced redundancy and voting are presented.

**LHC Beam Permit Loop** Fig. 5.12 shows as example the principle of the Beam Permit loop in the LHC BIS (31). The information transmitted by the loop is a flag called BEAM PERMIT, which can take the Boolean values TRUE or FALSE reflecting the presence or absence of the correct value of the frequency in the loop. The frequency is generated by a frequency generator (FSM / CIBG). If all switches in the loop are closed, each requiring the LOCAL BEAM PERMIT signal to be TRUE, the frequency propagates and is read and communicated by the detectors as BEAM PERMIT TRUE.

The BEAM PERMIT signal is used by the LHC injection system and the LHC and SPS Beam Dumping System (LBDS / SPS BDS) to control the activation of injection and extraction kicker magnets. BEAM PERMIT TRUE means all the (local) systems interfaced with the loop allow for beam operation. If either one of the LOCAL

## 5. AVAILABILITY-DRIVEN DESIGN OF MPS FOR PARTICLE ACCELERATORS

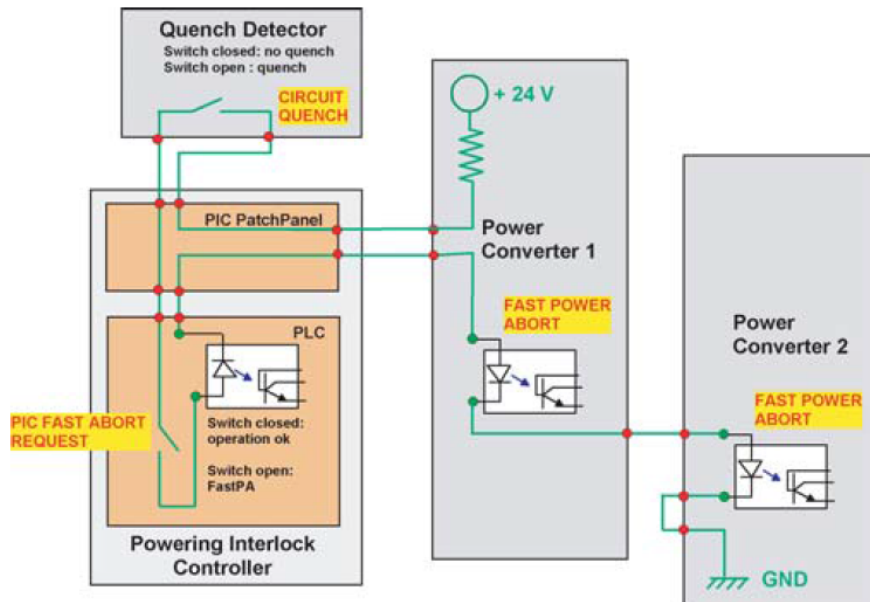

Figure 5.13: Schematic view of the LHC quench loop.

BEAM PERMIT signal turns FALSE, indicating a non-nominal condition detected by that system, BEAM PERMIT turns FALSE. This results in the activation of the beam extraction kicker magnets by the LBDS. The detection of non-nominal conditions and failures and the correct transmission of the information are crucial for machine protection. The beam permit signal is hereby composed of signals in two redundant beam permit loops, each of which has its own frequency generator. If either of the two loops indicates a failure, the BEAM PERMIT turns FALSE, following a one-out-of-two logic (1o2). For most of LHC operation the beam permits of the two beams are coupled. When the loops are coupled and any of the four circuits is opened, BEAM PERMIT becomes FALSE for both beams.

**LHC Circuit Quench Loop** The transition of a superconducting magnet to the normal conducting state (i.e. quench) is detected by the magnet protection system. In case of a quench in any part of the magnet powering circuit, a (local) quench detector provides the information to the quench loop, which in turn transmits it to the relevant systems (74). Figure 5.13 shows the principle of the Circuit Quench loop in the LHC magnet protection system, controlling a magnet powering circuit (75). It connects the

## 5.2 Definition of Interlock System Architectures

---

three main systems, namely quench detection system (that includes a number of quench detectors), power converters and powering interlock controller in series.

In case of a quench, the CIRCUIT QUENCH signal in the quench detection system leads to the opening of the related switch. The resulting absence of current in the loop is detected by the power converters as a FAST POWER ABORT signal, which triggers the shutdown of the power converters. From the MPS point of view, a quench detection is followed by the firing of the quench heaters. These are strips placed above the magnet coils which allow distributing the quench over a big surface of the magnet to reduce the energy density. The current in the circuit is extracted via the opening of switches belonging to the energy extraction system and dumped in a resistor, that allows dissipating the energy into heat. The absence of current is also detected by the powering interlock controller which in turn generates a PIC FAST ABORT REQUEST signal. This duplication is implemented for redundancy reasons and to assure that an operator needs to close this switch for continuing operation. The PIC FAST ABORT REQUEST signal is also used to shut down power converters in other magnet powering circuits, as well as for diagnostics. Unlike the beam permit loop, the individual quench loop does not include redundancy. There is only one quench loop control circuit per magnet powering circuit (one-out-of-one, 1oo1). The loop can obviously be opened by any of the three main systems. In addition, a powering interlock controller can control several loops. Hence, in case of a quench in a particular powering circuit, the powering interlock controller can initiate a PIC FAST ABORT REQUEST signal for other powering circuits in the same cryogenic sector (powering subsector) to avoid that quenches propagate from one circuit to another, e.g. through warming of the helium. For powering circuits with a large number of magnets - e.g. the main dipole and main quadrupole powering circuits - the quench detection is not based on a single detector but on a series of detectors that monitor magnets, busbars and current leads. In that case, the detectors are themselves connected through a current loop and interfaced with the quench loop in a global detection unit. In addition to the circuit quench loop, there are other loops used between the powering interlock system, the power converters and the quench protection system, transmitting different bits of information.

## 5. AVAILABILITY-DRIVEN DESIGN OF MPS FOR PARTICLE ACCELERATORS

Figure 5.14: Example of an open signal path model.

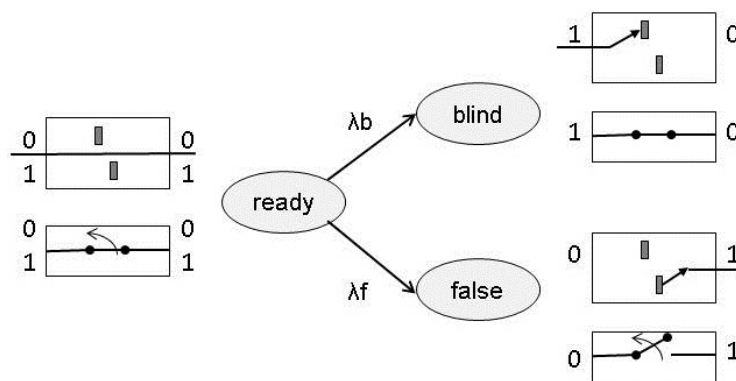

Figure 5.15: Markov model of the basic loop component.

### 5.2.3.1 Quench Loop Architectures

The objective of the study on interlock loop architectures is to quantify the performance of different architectures in terms of machine safety and availability (76). To account for this, a Markov description of components' failure behaviour was used in an open signal path model (Fig. 5.14).

Each component of the loop (sensor, actuator, etc.) is modelled as a switch that can interrupt the signal path, ideally with the scope of turning the machine to a safe state. In this representation the nominal function of the system is fulfilled if the signal is able to propagate from the Start (S) to the End (E). The state of the switches is a boolean variable (1 - close, 0 - open). The Markov model of the switch is shown in Fig. 5.15.

Components are normally in the 'ready' state. Each component can open following a spurious ('false') detection. The component can also turn into a state where opening is inhibited ('blind'). The transition to one of these two alternative states occurs

**Figure 5.16:** Markov model of the virtual demand component.

according to two different failure rates,  $\lambda_b$  and  $\lambda_f$ , assuming exponentially distributed failures. The assumption is that the two failure states ('blind' and 'false') are exclusive, i.e. no transition exists between the two.

The system demand, i.e. the occurrence of a dangerous machine state, is modelled by an additional virtual component with two states (Fig 5.16). 'Silent' is the default state, when no dangerous configurations for the machine are present. 'System demanding' is the state representing the need for an emergency action to be taken by the interlock system. The transition to the 'System demanding' state is also assumed to be exponentially distributed, with a demand rate  $X$ . Based on the open path model, four operational scenarios can be identified over a given observation time ( $T_f$ ) (i.e. a 'mission') of the system:

1. **Mission completed:** No false trigger, successful emergency shutdown or missed emergency shutdown.
2. **False trigger:** False signal triggered in system component and transmitted to E, with no demand signal.
3. **Demand success:** demand signal triggered in S and propagated to E.
4. **Demand missed:** demand signal triggered in S and not propagated to E.

At time 0, all components are in their nominal state, i.e. the switches are 'ready' and the demand component is 'silent'. The observation of the system is stopped if one among scenarios 2, 3 or 4 occurs. If this is not the case, the given observation time  $T_f$  is reached, leading to scenario 1. Scenario 1 represents nominal system operation (no demand for emergency shutdowns nor spurious emergency shutdowns). Maximizing the occurrence of this scenario implies optimizing Machine Availability. Scenario 4 is

## 5. AVAILABILITY-DRIVEN DESIGN OF MPS FOR PARTICLE ACCELERATORS

---

**Figure 5.17:** Interlock loop model with three lines, each featuring 4 components, and a demand block. Six architectures are considered based on this representation (1001, 1002, 2002, 1003, 3003, 2003).

instead the worst case scenario where there the emergency shutdown is not executed following a system demand. This scenario gives a direct measure of the system Safety. The model allows estimating the probabilities for the occurrence of the four above scenarios as a function of relevant input parameters. These are:

**Observation Time** [ $T_f$ ]: The time over which the system behaviour is evaluated.

**False rate** [ $\lambda_f$ ]: the rate of spurious opening of each loop component.

**Blind rate** [ $\lambda_b$ ]: the rate of blind failure of each loop component.

**Demand rate** [ $\mathbf{X}$ ]: the rate for demands of emergency shutdowns.

A description of the models for different loop architectures and voting strategies is presented. As a first step, six architectures for the quench loop with fault-free voting are considered (Fig.5.17). The loop is composed of up to three identical lines, featuring the same number of components, and a demand block.

1001: single-line architecture, no redundancy

1002: two redundant lines with 1-out-of-2 logic

2002: two redundant lines with 2-out-of-2 logic

## 5.2 Definition of Interlock System Architectures

---

1oo3: three redundant lines with 1-out-of-3 logic

2oo3: three redundant lines with 2-out-of-3 voting

3oo3: three redundant lines with 3-out-of-3 logic

The definition of the basic scenarios proposed above applies directly only to the 1oo1 architecture. Definitions need to be extended for the other architectures. Taking the 2oo3 architecture as an example, a mission completed will occur if at least 2 lines of the loop will still be closed (i.e. not failed) at the end of the observation time and no emergency shutdown request was issued. Similarly a false trigger will be identified if at least 2 lines are open without an emergency shutdown request. A demand success will be identified if at least 2 lines open (i.e. fail) following an emergency shutdown request. A missed emergency shutdown will occur in case less than 2 lines open following a shutdown request.

Both analytical (76) and simulation-based models for the described systems were developed. The analytical model is based on probability theory and considers the chosen probability density functions in different architectures to calculate the probability of occurrence of each of the six scenarios. The simulation approach is Monte Carlo-based and is implemented in MATLAB (51) or Simulink (77). The model allows reproducing the signal propagation in the different architectures, according to randomly generated failures and demands, given the chosen input parameters. The system behaviour is evaluated over the observation time and scenarios identified based on the configuration of the different loop lines. The Simulink model is used when the model complexity would be too high to be managed by the analytical approach or the corresponding MATLAB implementation. Nevertheless the calculation in Simulink is the slowest among the three. In the following, unless explicitly specified, results are produced with the analytical model. The advantage of this approach is that the occurrence of rare events can be easily taken into account, whereas with simulation a large number of cycles is necessary to have significant statistics for comparison. A thorough process of verification of the analytical results has been performed by reproducing the probability of occurrence of the four scenarios also via the simulation models. The absolute errors lie in the range between 1E-7 and 1E-3 for the first three scenarios and between 1E-8 and 1E-4 for the demand missed.

## 5. AVAILABILITY-DRIVEN DESIGN OF MPS FOR PARTICLE ACCELERATORS

---

$T_f$	720 h
$\lambda_b$	$10^{-5}h^{-1}$
$\lambda_f$	$10^{-4}h^{-1}$
X	$2 * 10^{-4}h^{-1}$

**Table 5.6:** Reference input parameters for interlock loop studies.

The reference input parameters for the calculations are shown in Table 5.6.

The results for the six architectures are then presented in Table 5.7.

	1oo1	1oo2	2oo2	1oo3	2oo3	3oo3
Mission completed	6.50E-01	4.88E-01	8.12E-01	3.66E-01	7.31E-01	8.52E-01
False trigger	2.33E-01	4.10E-01	5.68E-02	5.43E-01	1.42E-01	1.40E-02
Demand success	1.17E-01	1.03E-01	1.30E-01	9.08E-02	1.27E-01	1.32E-01
Demand missed	3.99E-04	1.54E-06	7.97E-04	6.57E-09	4.60E-06	1.19E-03

**Table 5.7:** Predicted occurrence of the four scenarios through the analytical model for the six selected loop architectures.

Results highlight the 2oo3 loop architecture being the best compromise between availability (scenario 1) and safety (scenario 4). If the primary focus of the system is on safety, then the best architecture would be 1oo3, showing the lowest probability of occurrence of scenario 4. If the focus is on availability, then the 3oo3 architecture maximizes the probability of scenario 1.

### 5.2.3.2 Sensor Interface and Quench Loop Architectures

Based on these results for the loop architecture, the study can be further extended by taking into account the configuration of sensors that would represent the best interface between the loop elements and the demand block. The 2oo3 architecture is assumed as the reference at the loop level in this analysis. This leads to the definition of 8 new system architectures, including different sensor interfaces and voting (Fig.5.18). The components at the interface level are assumed to have the same failure behaviour as the loop components (the same failure model and input parameters are taken). The assumption is still to have fault-free voting at this stage.

The calculation of the probability of occurrence of the four scenarios introduced above yields the results in Table 5.8.

## 5.2 Definition of Interlock System Architectures

**Figure 5.18:** Interface and loop models. Eight architectures result from the combination of different voting strategies at the interface level. 2oo3 voting is assumed at the loop level.

	A	B1	B2	C1	C2	C3	C0
Mission completed	7.95E-01	7.40E-01	8.50E-01	6.89E-01	8.42E-01	8.54E-01	8.24E-01
False trigger	7.62E-02	1.36E-01	1.68E-02	1.91E-01	2.48E-02	1.28E-02	4.44E-02
Demand success	1.28E-01	1.25E-01	1.32E-01	1.20E-01	1.33E-01	1.32E-02	1.32E-01
Demand missed	4.62E-04	7.96E-06	9.16E-04	5.96E-06	1.25E-05	1.37E-03	2.31E-05

**Table 5.8:** Predicted occurrence of the four scenarios through the analytical model for the eight selected interface architectures.

As done for the loop studies, it can be observed that the 1oo3 architecture at the interface level (C1) represents the best choice for safety (lowest probability of scenario 4). The 3oo3 architecture at the interface level (C3) is instead the best choice to preserve availability. Architecture C2, that features 2oo3 voting both at the loop as well as the interface level, is the best compromise between safety and availability as it is among the best three architectures for both safety and availability. A comparable performance to C2 is achieved by architecture C0, without any voting strategy at the interface level. C0 needs a significantly lower amount of logic to be implemented and this poses the problem of quantifying the impact of the increased voting complexity of different architectures on safety and availability. This is done by considering error-prone voting, i.e. by assigning to the voting logic the same failure behaviour as the other components of the loop and interface. Table 5.9 highlights the results for the C0 and C2 architectures, with fault free voting, and C2 with error-prone voting. For the

## 5. AVAILABILITY-DRIVEN DESIGN OF MPS FOR PARTICLE ACCELERATORS

---

latter the results are calculated through Monte Carlo simulations in MATLAB (1E8 iterations), due to the limitations of the analytical approach with increasing system complexity.

	C0	C2	C2 Error Prone
Mission completed	0.824	0.842	0.784
False trigger	0.044	0.025	0.087
Demand success	0.132	0.133	0.128
Demand missed	2.3E-05	1.2E-05	4.62E-04

**Table 5.9:** Predicted occurrence of the four scenarios for architectures C0, C2 and C2 Error Prone. For C2 Error Prone results are calculated through Monte Carlo simulations in MATLAB (1E8 iterations).

Results show that considering error prone-voting the C2 option exhibits worse performance than C0 (and C2, as expected) both in terms of safety and availability. C2 Error Prone shows about a factor 10 higher probability of occurrence of scenario 4. The error-prone voting introduces a reliability bottle neck for the architecture. The possibility of introducing redundancy for the component implementing the voting logic was therefore studied. Three redundant voting blocks were considered in 2oo3 configuration (Fig.5.19) and simulations were performed based on the Simulink implementation of the model, which only allowed a limited number of simulation iterations.

Results show an increase of Mission Completed (comparable to C0) and the decrease of the Demand Missed probability by one order of magnitude, back to the range of C0 and C2. This result is still based on the assumption that all components have the same failure behaviour, i.e. same failure model and same input parameters  $\lambda_f$  and  $\lambda_b$ . This is not realistic if one considers the hardware implementation of the voting logic, based on few logic gates, and current technologies. Three hardware implementations were then considered for the voting logic (Fig.5.20).

The first option is the basic implementation of the 2oo3 logic (3 AND gates and one OR gate). The second adds redundancy at the level of the OR gates in order to have each loop line connected to one output of an OR gate. The third considers full redundancy, by triplicating the implementation of the first option. Each gate was assumed to be an error-prone component at this stage, but in this case both  $\lambda_f$  and

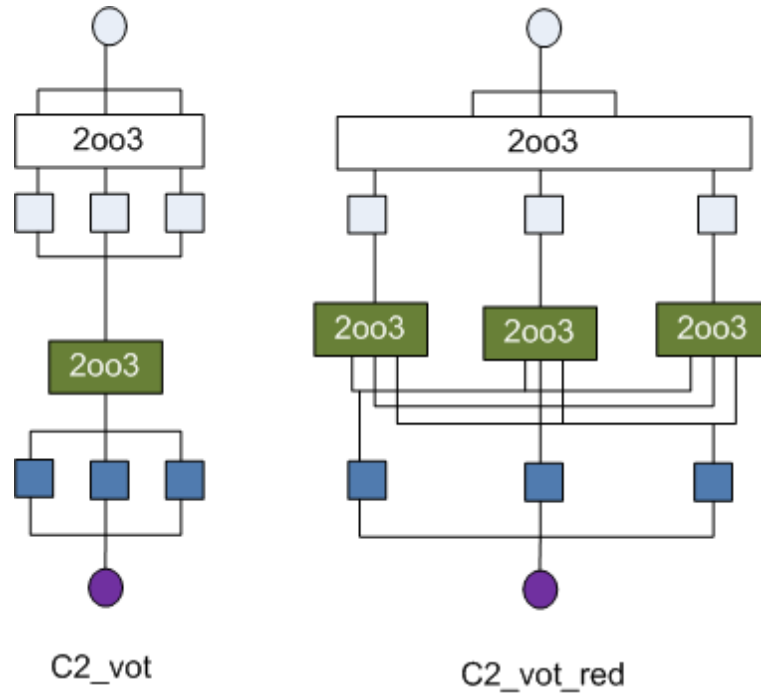

Figure 5.19: 2oo3 redundancy for error-prone voting.

Figure 5.20: 2oo3 logics implementations.

## 5. AVAILABILITY-DRIVEN DESIGN OF MPS FOR PARTICLE ACCELERATORS

---

$\lambda_b$  were assumed to be 10E-6/h (while keeping the other components at the reference input values).

With these assumptions, results for the C2 error-prone voting recover the performance of the C2 fault-free architecture (Table 5.9) for scenario 1. Both the first and second implementations show an increase of the probability of occurrence of scenario 4, whereas the third implementation didn't produce any 'demand missed', possibly indicating that also the probability for scenario 4 goes back to the range of the C2 fault-free architecture. It has to be noted that in this case result accuracy is limited by the low number of simulation runs (1E4).

An important outcome of this study is the identification of the 2oo3 voting being the best compromise between safety and availability. In view of future system developments for new facilities (e.g. ITER) and upgrades of existing systems with stringent safety and availability requirements, 2oo3 voting is recommended as the baseline for the design. Nevertheless in the decision for the final architecture choice other factors could play a crucial role, e.g. the cost of design, production and maintenance of a complex system.

### 5.2.4 Impact of Newly Designed Systems on Availability

During operation of an accelerator, it is not excluded that unpredicted failure modes might appear and require immediate mitigations to be deployed. In the worst case of a failure that could compromise machine safety, the design of new systems might be required to enhance the protection of the machine.

In 3.3.1 it was explained that the LBDS is one of the most critical MPS of the LHC, as it is the only way to safely extract the LHC beams and send them to the beam dump. A critical failure of such system implies that the beam dump could not be performed. Fig. 5.21 shows a schematic view of the LBDS and its subsystems. Two redundant front-end electronic systems (Trigger Synchronization Units, TSU) are interfaced with the BIS to detect the necessity of triggering a beam dump. The BIS is composed of two electronic sub-systems, the Controls Interlocks Beam Manager (CIBM) and the Controls Interlocks Beam Generator (CIBG). An incoming beam dump request has to be propagated via the Trigger Fan Out (TFO) to the 15 kicker magnets that extract the beam from the LHC ring to the transfer lines towards the beam dump block. The rise time of the kicker magnets is 3  $\mu$ s, therefore a particle free gap (abort gap) is needed in the beam for a safe beam extraction (78). The TSUs are also in charge

## 5.2 Definition of Interlock System Architectures

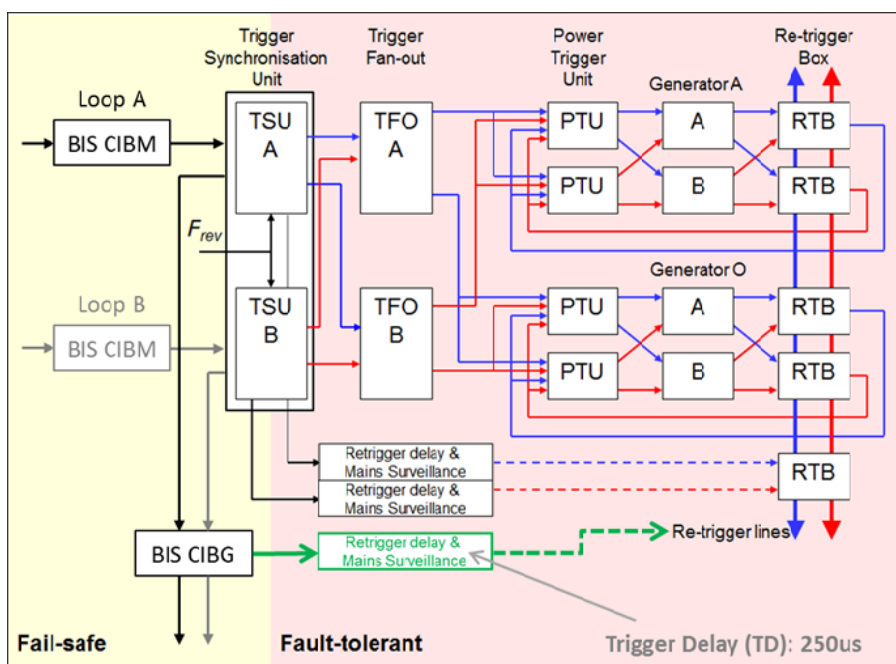

Figure 5.21: Schematic representation of the LBDS functionality.

of synchronizing the beam dump request with the abort gap. At least 14 out of 15 magnets have to reach the design field in order to perform a nominal beam dump (29). To ensure the execution of a beam dump upon request redundancy was added in the system in order to ensure that all the Power Trigger Unit (PTU) generate a pulse to power the kicker magnets. Furthermore, as an additional layer of protection, so-called retriggering boxes (RTB) ensure that whenever a kicker is fired all others are also activated via the PTUs. This mitigates the consequences of a spurious kicker firing by performing an asynchronous beam dump, i.e. a dump which is not synchronized with the abort gap. In addition, every time a dump request is detected from the TSUs, these also send a delayed signal ( $200 \mu\text{s}$ ) to the retriggering lines via a Trigger Delay Unit (TDU) to perform a delayed asynchronous beam dump in case the main chain (TFO and PTU) fails. The probability of occurrence of an asynchronous beam dump must be minimized. The consequences of an asynchronous beam dump are mitigated by the presence of suitable passive protection of the extraction region, designed to cope with such failure scenario. It has been estimated that one such event per year can occur for the LHC.

In 2012 a common-mode powering failure of the TSU was discovered during tests

## 5. AVAILABILITY-DRIVEN DESIGN OF MPS FOR PARTICLE ACCELERATORS

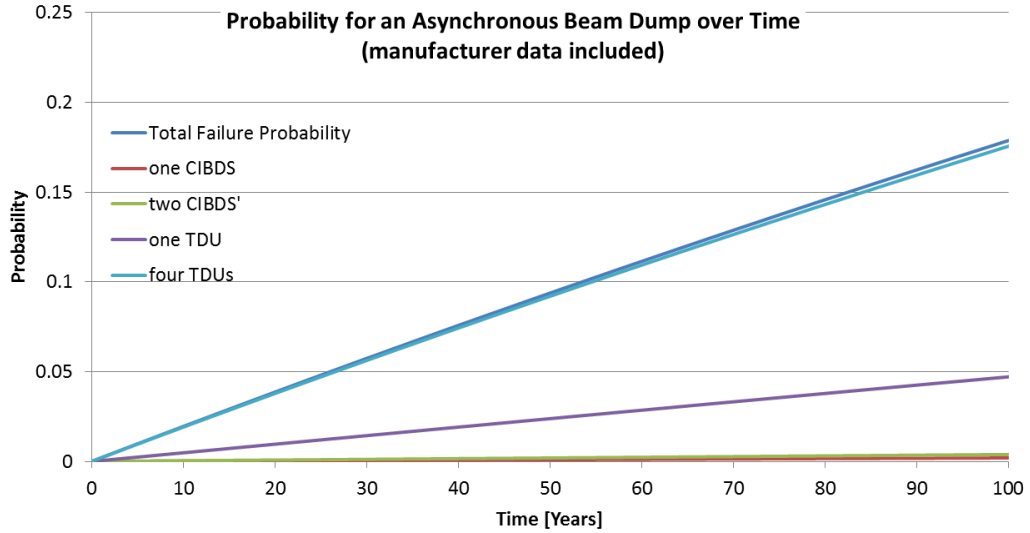

---

and the machine was stopped as a precautionary measure. A temporary monitoring system was deployed to recover nominal operation, while a new hardware system was being designed to cope with the new failure mode. The design of the TSU is very complex. As a long-term solution it was decided to have a totally independent system from the TSU capable of triggering a beam dump and implement a redundant link (CIBDS) from the BIS to the LBDS that would by-pass the front-end electronics, directly triggering a beam dump (asynchronous) even in case of a common-mode failure of the redundant TSU units (79). This additional link would only trigger an asynchronous beam dump after a predefined delay with respect to the occurrence of the nominal trigger by the TSU. The likelihood of a safe extraction of the LHC is clearly enhanced by this additional layer of protection, but the new system also adds complexity, with a potential of compromising LHC availability in case of spurious hardware failures. The specifications of the new system were therefore expressed in terms of additional number of false dumps per year due to the new link. It was defined as acceptable for the new link to provoke not more than one asynchronous beam dump in ten years and two (false) synchronous beam dumps per year. A quantitative analysis of the expected increase of the percentage of false dumps was performed. A component-level failure analysis of the newly designed hardware was performed in order to infer the expected increase of false dumps per year (80). It was stressed in 4.1 that a top down approach for MPS design is generally the most suitable. In the case of a previously operating system, as the LHC, the knowledge gained through experience allows quantifying the consequences of component failure modes with a high degree of precision, therefore a bottom up approach is valuable in this context. The analysis was carried out in Isograph (52), based on the estimates of component failure rates from the MIL-HBK-217D (see 4.2.1). The consequences of the different failure modes of each component on the system behaviour were evaluated by Cadence OrCAD simulations (81). The MIL-HBK-217D provides conservative estimates of failure rates, therefore it is preferred to use manufacturer's data on the expected failure rate of a component, when available.

The analysis showed that while the introduction of an additional layer of protection will significantly improve LBDS safety, the impact on LHC availability will be marginal. The failure rate associated to the occurrence of an asynchronous beam dump is 224.68 FIT. The failure rate associated to the occurrence of a synchronous beam dump is 621.94 FIT. This translates in ten years of operation in  $19.7 * 10^{-3}$  asynchronous beam

## 5.2 Definition of Interlock System Architectures

**Figure 5.22:** Expected probability of occurrence of an asynchronous beam dump over time due to the additional designed layer of protection (CIBDS and additional TDUs). Manufacturer data for component failures is assumed when available.

dumps and  $5.45 \times 10^{-3}$  synchronous beam dumps expected due to the newly designed system. Fig. 5.22 shows for example the expected probability of occurrence of an asynchronous beam dump over time. In both cases, the results have a minor impact on LBDS figures for the total number of false dumps, resulting orders of magnitude below the tolerated values. This was expected, as the additional complexity added by the new system is negligible if compared with the complexity of whole LBDS.

## 5. AVAILABILITY-DRIVEN DESIGN OF MPS FOR PARTICLE ACCELERATORS

---

# 6

## Availability-driven Optimization of Accelerator Performance

Chapter 6 focuses on accelerator exploitation and performance optimization through availability. The LHC is taken as a reference for the analysis.

### 6.1 2010-2012 LHC performance

In this paragraph the performance of the LHC will be discussed and related to system availability during LHC run 1 (2010-2012). A particular emphasis will be put on 2012, as this was the most reproducible and stable year of operation and represents the reference for the future LHC runs.

#### 6.1.1 Availability and Integrated Luminosity

The main figure of merit of a particle collider is the integrated luminosity  $L$ . This is a direct measure of the number of interesting events per second  $R_E$  recorded by the experiments, that can be calculated knowing the probability (i.e. the so-called production cross-section  $\sigma_p$ ) of generating such events during the collision process (Eq. 6.1).

$$R_E = L * \sigma_p \tag{6.1}$$

A common expression for luminosity is given in Eq. 6.2 (83):

## 6. AVAILABILITY-DRIVEN OPTIMIZATION OF ACCELERATOR PERFORMANCE

$$L = \frac{n_b N_b^2 f_{rev}}{4\pi\sigma^*} \quad (6.2)$$

where  $n_b$  is the number of bunches per beam,  $N_b$  the number of particles per bunch,  $f_{rev}$  the revolution frequency and  $\sigma^*$  the transverse beam size at the interaction point. The latter is given by:

$$\sigma^* = \sqrt{\beta^* \epsilon} \quad (6.3)$$

where  $\beta^*$  is the amplitude of the beam envelope at the interaction points and  $\epsilon$  the emittance, which is considered in first approximation a constant property of the beam (86).

The so-called peak luminosity is achieved at the beginning of collisions. Afterwards luminosity exponentially decays, ideally only due to particle burn-off. Observations demonstrate that other factors have an impact on the luminosity decay (82) (83). The time constant of the exponential decay is called luminosity lifetime. The integral over time of the luminosity exponential function is the integrated luminosity.

**Figure 6.1:** The LHC cycle. The dipole circuit current is shown in green. Intensities for beam 1 and beam 2 are reported in blue and red, respectively. Values shown are nominal LHC parameters for operation at 7 TeV with full intensity.

Luminosity is only produced when beams are colliding, i.e. in a specific phase of the LHC cycle called ‘stable beams’. Fig. 6.1 shows the different phases of the

LHC cycle. The beams extracted from the SPS at 450 GeV are sent to the LHC via dedicated transfer lines. A safe (i.e. with negligible damage potential) probe beam to verify the correct behaviour of all accelerator system is injected first (84). Only afterwards injection of full intensity beams is allowed ('injection') and the machine is filled with proton bunches. Different filling schemes can be followed, with a variable number of proton bunches and a variable spacing in time between two consecutive bunches (i.e. the bunch spacing). The maximum number of bunches in the LHC is 2808 with 25 ns bunch spacing. In the 2010-2012 run, 50 ns bunch spacing was adopted as the operational baseline. The injection process takes about 50 min (85). The magnetic field in the dipole magnets is ramped up while accelerating particles to LHC top energy ('ramp-up'). In 2010-2012 the energy has been limited to a maximum of 4 TeV and the minimum ramp time was about 770 s. For LHC run 2 the energy will be increased to 6.5 TeV, requiring a ramp time of 1300 s. Once the beams reach top energy, the beam size at the interaction points  $\sigma^*$  is reduced to improve the collision rate ('squeeze'). This is achieved by reducing the  $\beta^*$ . Up to this point in the cycle the beams are kept separated and therefore do not collide.

Finally the beams are put in collision ('adjust'). Collisions ideally take place for several hours and data is collected by the experiments ('stable beams'). Beams going through the LHC cycle are referred to as a machine 'fill'. Fig. 6.2 shows the length probability distribution of stable beams in 2012. Many fills were dumped soon after reaching stable beams, mainly due to the fact that beam losses are highest at the beginning of the collisions. Only few fills reach more than 10 h in stable beams, as 70 % are dumped earlier after a detection of a failure by the MPS or by the operators. Once beams are extracted from the LHC, magnets are ramped down to prepare the injection of beams for the next fill ('ramp-down' and 'pre-injection').

According to the definition given in 3.1, the LHC is only available for physics during stable beams, when luminosity is produced. The rest of the LHC cycle is part of the turnaround time and should therefore be minimized. The scope of this chapter is to quantify the impact of accelerator availability on luminosity production. In the past the most efficient way to increase the integrated luminosity was to increase the peak luminosity (83). The limit to the peak luminosity that the LHC can reach is determined by the event pile-up in the experiments, namely by the number of simultaneous events that can be processed and recorded by the experiments measuring the outcome of the

## 6. AVAILABILITY-DRIVEN OPTIMIZATION OF ACCELERATOR PERFORMANCE

---

Figure 6.2: 2012 LHC stable beams distribution.

collisions. Technological limitations of the experiments set a constraint on the pile-up and therefore on the peak luminosity. New strategies have to be defined to overcome this limitation. Given the fixed peak luminosity, the integrated luminosity can be maximized by extending the time in stable beams, i.e. by maximising the Availability for Physics (3.1). Due to a limited luminosity lifetime, the duration of stable beams nevertheless should not be indefinitely extended. An optimum point in time for balancing the loss of integrated luminosity resulting from the luminosity exponential decay and from the turnaround time can be calculated. This point in time is a function of the average fault time, the turnaround time and the luminosity lifetime. As will be discussed in the present chapter, the optimization of availability poses major challenges.

### 6.1.2 Study of 2010-2012 data

As explained in the previous paragraph, a LHC fill can be aborted by a system failure - through the MPS - or intentionally by the operators for optimization of luminosity production. The Machine Failure Rate (MFR) is defined as in Eq. 6.4, where  $N_F$  is the number of fills dumped due to failures and  $N_P$  is the total number of physics fills.

$$MFR = \frac{N_F}{N_P} \quad (6.4)$$

For fills terminated by failures a detailed analysis of the individual dump causes was carried out. The repartition of dump causes for the years 2010-2012 is shown in Figs 6.3, 6.4, 6.5. The data was retrieved in the PM database (87). The dumps were classified as follows:

- Operations (purple): the beam dump is triggered by LHC operators.
- Beam (light-blue): beam effects, as instabilities or beam losses, lead to an interlock response and to a beam dump.
- Equipment failure (green): the beam dump is triggered by a malfunction of an accelerator equipment (e.g. the vacuum system).
- Experiments (orange): the beam dump is triggered by interlocks monitoring the status of LHC experiments.
- External (purple): the beam dump is initiated by the detected lack of necessary external resources for the CERN complex (mainly electrical supply).

This classification can be refined. ‘Beam’ can be split into beam losses, orbit drifts and UFOs (Unidentified Falling Objects). UFOs are dust particles in the beam pipe that generate losses when intercepting the beam (45) (46), possibly leading to a beam dump.

‘Equipment failures’ are divided into MPS, controls, Safety and Machine. MPS includes all the LHC protection systems (BIS, LBDS, PIC, QPS, BLMs, Collimation, see 3.3.1). ‘Controls’ accounts for all software-related failures. ‘Safety’ has here to be intended as personnel protection. The remaining part considers all other accelerator systems (e.g. the cryogenic and vacuum systems).

‘Operations’ includes so-called End of Fills (EOF), namely dumps initiated by operators for luminosity optimization. Errors from operators are also considered, as well as machine tests and developments (MDs). MDs are dedicated beam times during the accelerator run allocated for studies of new machine parameters and relevant physics

## 6. AVAILABILITY-DRIVEN OPTIMIZATION OF ACCELERATOR PERFORMANCE

phenomena (e.g. study of quench levels), which do not contribute to luminosity production.

Excluding EOF and external dump causes, all other dumps are due to CERN systems and cause unnecessary un-availability of the LHC. The occurrence of such events must therefore be minimized. Among unnecessary dumps, spurious failures of the MPS leading to a dump are referred to as 'false dumps'.

**Figure 6.3:** Repartition of 2010 dump causes from the PM database.

Table 6.1 shows the absolute number of times an LHC system caused a beam dump in 2012. The color code adopted in Fig. 6.5 was kept to relate each system to the previously defined categories.

Comparing the dump causes of 2010, 2011 and 2012 one can see that the percentage of EOF consistently increases over the three years. This indicates a clear learning trend and an improvement in operational practices due to an increased machine understanding. The MFR decreased from 80 % in 2010 to 70 % in 2012. Similarly, the number of fills that were injected in the LHC increased from 355 in 2010 to 585 in 2012. These figures were achieved while increasing the peak luminosity (higher intensity, lower  $\beta^*$ ).

## 6.1 2010-2012 LHC performance

Controls	12	Beam: Orbit	1

**Table 6.1:** 2012 dump cause occurrence by system.

Higher beam intensities can nevertheless have an impact on beam losses, for example due to the excitation of beam instabilities. This is confirmed by the related statistics.

The performance of the MPS has been relatively stable over the three years. Only a slight increase of MPS-induced faults can be observed. This could be explained by the increased radiation levels experienced by exposed electronic systems in the LHC tunnel (e.g. QPS) due to the increased luminosity.

Statistics on the occurrence of faults preventing LHC operation have to be complemented with data related to the machine fault time. Fig. 6.6 shows the distribution of fault times associated to the occurrence of all system failures in 2012. Most of the faults are cleared within few hours, but some outliers require major interventions that can last up to several days. These are typically associated to concurrent failures of different systems caused by thunderstorms or power cuts, requiring the cryogenic system to recover operating conditions.

A deeper analysis of the system fault times was performed, based on data from the operation e-Logbook (Table 6.2). The beam-related category does not appear here, as it is assumed that immediate recovery of operating conditions is possible following beam losses correctly detected by the MPS. In the table, LHC injectors are also seen as 'causes', as they are directly affecting LHC availability if they do not provide beams.

## 6. AVAILABILITY-DRIVEN OPTIMIZATION OF ACCELERATOR PERFORMANCE

---

Considering the combined figures of dump cause occurrence and absolute fault time, the three systems responsible for the largest contributions to LHC un-availability are the cryogenic system, the QPS and the power converter system.

For MPS systems, statistics on the first three years of LHC operation are extremely valuable, as they allow comparing observations with reliability predictions obtained by dedicated models. These were developed during the LHC design phase (2005). In particular, predictions were expressed for each MPS sub-system in terms of tolerable number of unsafe events (i.e. potentially leading to catastrophic damage of equipment) and false dumps per year (28).

As a first approximation, a top level view of system failures is sufficient to assess the impact of each system on the overall accelerator availability and make assumptions on the achieved level of safety. Table 6.3 shows the comparison between the forecasted number of yearly false beam dumps and the actual observations in LHC run 1. Systems not respecting the predicted range are highlighted in red.

System	Predicted 2005	Observed 2010	Observed 2011	Observed 2012
LBDS	6.8 +- 3.6	9	11	4
BIS	0.5 +- 0.4	2	1	0
BLM	17.0 +- 4.0	0	4	15
PIC	1.5 +- 1.2	2	5	0
QPS	15.8 +- 3.9	24	48	56
SIS	not calculated	4	2	4

**Table 6.3:** Comparison of LHC false dumps predictions (2005) with observed false dumps during Run 1.

In general a good agreement can be seen between predictions and observations. Only the QPS is consistently out of the foreseen range. Radiation effects on electronics (R2E) causing Single Event Upsets (SEU) were not accounted in the original calculations. These play a dominating role in the statistics related to QPS, as electronics has to be located in the tunnel and is therefore directly exposed to radiation. About half of the total number of QPS faults have been proven to be due to R2E (88). Considering this, the QPS is respecting the foreseen range of false dumps per year. Also other MPS

systems were affected by radiation effects and were relocated already during LHC run 1 to avoid R2E-induced downtime.

The fact that predictions related to availability are in line with observations gives good confidence in the developed reliability models and leads to the qualitative assumption that also the desired safety levels are respected. Nevertheless verifying this aspect rigorously requires more accurate studies that are outside the scope of this work. A detailed study of LBDS safety and availability during LHC run 1 was performed and are results presented in (89).

The QPS is not the only system whose availability performance has been strongly affected by R2E effects. Various types of electronic devices belonging to different systems were located during the first LHC run in areas exposed to radiation. A detailed analysis of each failure suspected to be caused by R2E has been carried out (88). A total of 57 beam dumps during the 2012 LHC run was caused by SEUs on different systems. A distinction is made between ‘soft’ SEU, not requiring the replacement of the faulty electronic device, and ‘hard’ SEU, requiring a repair action. These may require access in the tunnel for diagnostics and reset. Fig. 6.7 shows the fault time distribution due to R2E-induced failures. Fault times range from about 30 minutes (in case of soft SEUs) to many hours for failures involving the controls of the cryogenic system.

**Figure 6.7:** Fault time distribution for R2E-induced failures in 2012.

## 6. AVAILABILITY-DRIVEN OPTIMIZATION OF ACCELERATOR PERFORMANCE

---

### 6.1.3 Integrated Luminosity and Availability: Analytical Model

A simple analytical description of luminosity as a function of availability can be developed based on the studies of availability figures from LHC run 1.

The distribution of stable beams (Fig. 6.2) can be approximated by an exponential Probability Density Function (PDF) (90), as shown in Eq. 6.5. This is a first order approximation made for simplicity that nevertheless yields valuable results.

$$f(x) = \frac{1}{\tau_f} e^{-\frac{x}{\tau_f}} \quad (6.5)$$

The average time in stable beams is given by:

$$T_f = \int_0^{\infty} f(x) dx \quad (6.6)$$

The instantaneous luminosity exhibits an exponential decay over time (see 6.1.1), as expressed in Eq. 6.7.

$$L(x) = L_p e^{-\frac{x}{\tau_f}} \quad (6.7)$$

Combining Eq. 6.5 and Eq. 6.7, a convenient analytical calculation of the average integrated luminosity per fill can be derived (91). This is given in Eq.s 6.8 and 6.9.

$$\langle L_{Int} \rangle = \int_0^{\infty} L_{Int}(t) f(t) dt = L_p \frac{\tau_L}{\tau_f} \int_0^{\infty} (1 - e^{-\frac{x}{\tau_L}}) e^{-\frac{x}{\tau_f}} dt \quad (6.8)$$

$$\langle L_{Int} \rangle = L_p \frac{\tau_L}{\tau_f} \left( \tau_f - \frac{\tau_f \tau_L}{\tau_f + \tau_L} \right) = L_p \frac{\tau_L \tau_f}{\tau_f + \tau_L} = L_p \tau_f e \quad (6.9)$$

The number of physics fills per year  $N_f$  can be deduced from the average fault time ( $T_{FAT}$ ), the average turnaround time ( $T_{TAT}$ ) and the total length of the LHC run  $T_{run}$ . As a result, the yearly integrated luminosity is given in Eq. 6.10.

$$\langle L_{Int} \rangle_{run} = N_f \langle L_{Int} \rangle = \frac{T_{run}}{T_f + T_{FAT} + T_{TAT}} \langle L_{Int} \rangle \quad (6.10)$$

Table 6.4 shows the baseline input parameters of the model for the calculation of the 2012 integrated luminosity. The delivered luminosity to the experiments in 2012 amounted to 23.27 [ $fb^{-1}$ ], while the analytical model yields 24.9 [ $fb^{-1}$ ]. Despite the strong assumptions made for simplicity, the model is able to reproduce the yearly luminosity with an accuracy of 5 %.

Parameter	Value
Mean fill length $T_f$ [h]	6.1
Average Turnaround $T_{tat}$ [h]	5.5
Average Fault Time $T_{fat}$ [h]	6.9
Mean peak luminosity $\mathfrak{L}_p$ [ $cm^{-2}s^{-1}$ ]	$6.28 \times 10^{33}$
Mean luminosity lifetime $\tau_L$ [h]	10
Days of operation	200
Total integrated luminosity $\langle \mathfrak{L}_{Int} \rangle_{run}$ [ $fb^{-1}$ ]	24.9

**Table 6.4:** 2012 LHC operational parameters and predicted integrated luminosity.

#### 6.1.4 Integrated Luminosity and Availability: Monte Carlo Model

A Monte Carlo model for reproducing a realistic timeline of LHC operation was developed in MATLAB (51), based on the definitions given in 3.1 and on data from 2012. The model aims at calculating the impact of LHC availability on the integrated luminosity, to identify areas and systems to be improved and resulting in the largest benefit for luminosity production. The approach which was followed for the model development has been described in 4.3. The identified high-level machine states are 'machine in fault', 'turnaround' and 'stable beams'. The performance relevant state is 'stable beams', as luminosity is only produced in this phase of the LHC cycle. As pointed out in 6.1.2, both the duration of faults and their frequency have an impact on the luminosity production. The Monte Carlo model is capable of addressing this aspect quantitatively.

**Figure 6.8:** Example of timeline produced by the Monte Carlo model of LHC operation. All quantities in the drawing are randomly generated by the Monte Carlo model.

## 6. AVAILABILITY-DRIVEN OPTIMIZATION OF ACCELERATOR PERFORMANCE

The considered baseline to reproduce the LHC operational timeline are therefore the 2012 figures for turnaround time, fault time and stable beams. The distributions of 2012 fault times and stable beam lengths are shown in Fig. 6.6 and 6.2, respectively. The Monte Carlo model generates random numbers according to the given distributions and produces a sequence of turnaround, stable beam and fault times over a predefined time period. This principle is shown in Fig. 6.8.

**Figure 6.9:** Comparison of the instantaneous luminosity fit for the LHC fill 3135 in 2012.

Faults do not occur during every stable beams, as some fills are intentionally stopped by operators. An additional random number representing the machine failure rate allows including in the timeline a fault only after a given percentage of fills.

In order to quantify the yearly luminosity production, also statistics related to relevant beam parameters are necessary. In particular statistics on peak luminosities and luminosity lifetimes need to be considered. These were produced by adopting a single exponential fit for the instantaneous luminosities of all the fills in 2012. A single exponential fit was chosen over a double exponential for simplicity. The Monte Carlo model produces a random number for each of the parameters of the exponential. Fig. 6.9 shows the result of the fit of the instantaneous luminosity of fill 3135, both with a single exponential and a double exponential. It can be seen that the single exponential gives a worse fit of the data, as it underestimates the peak luminosity. As the model aims at reproducing the integrated luminosity, the relative error of the single exponential approach compared to the double exponential was calculated. The error is defined as in Eq. 6.11, where  $L_{INT1exp}$  is the integrated luminosity obtained by using

a single exponential fit and  $L_{INT2exp}$  using the double exponential.

$$ERROR_{REL} = \frac{L_{INT1exp} - L_{INT2exp}}{L_{INT1exp}} \quad (6.11)$$

**Figure 6.10:** Relative error distribution of a single exponential fit of the integrated luminosity.

The histogram of the relative error is shown in Fig. 6.10 for all fills in 2012. It can be seen that the error on the integrated luminosity is consistently below 1%. Two peaks can be seen, one around 0% and one around -0.2%. Fig 6.9 illustrates that for average stable beams durations (6 h), the underestimation of the peak luminosity is approximately compensated by the overestimation of the instantaneous luminosity towards the end of the fill, producing the peak around 0% in the error histogram. For fills longer than 8 h, as the one in the figure, the fit underestimates the instantaneous luminosity, leading to a negative relative error.

Results for a single exponential fit of all fills in 2012 are shown in Fig. 6.11. The figure highlights the fast intensity ramp-up of 2012, going from fill 2450 to 2650. In this phase, the total beam intensity was progressively increased from one fill to the next in order to reach top beam performance in steps. It can be seen that after each of the three technical stops (red dashed lines) few fills with lower intensities are injected in the LHC before going back to maximum peak luminosities. The luminosity lifetime ranges from

## 6. AVAILABILITY-DRIVEN OPTIMIZATION OF ACCELERATOR PERFORMANCE

---

15 to 5 h and exhibits a decreasing trend over the year. This can possibly be explained as a consequence of the increased intensity, leading to instabilities compromising the beam quality.

**Figure 6.11:** Peak luminosity (top) and luminosity lifetime (bottom) resulting from a single exponential fit of 2012 data recorded by LHC experiments. Red lines indicate a machine technical stop for maintenance.

The Monte Carlo model generates for every stable beams a random peak luminosity and luminosity lifetime (Fig. 6.8) and calculates the integral over the stable beams time. The process is repeated until the total run time is reached and the yearly integrated luminosity is derived by summing the individual contributions of each fill. The calculation is repeated an arbitrary number of times and the distribution of the predicted integrated luminosity over one year of LHC operation is produced. Unless differently specified, all results presented in this chapter refer to 1000 simulated cycles of 160 days of LHC operation, which are assumed to be the reference allocated time for physics. LHC operation in 2012 represents an exception to this, as the run was extended up to 200 days.

The model was also extended to account for the possibility of performing luminosity levelling in the early part of stable beams (92). This practice aims at overcoming the limitations imposed by events pile-up, by providing to the LHC experiments a lower luminosity than what could be theoretically achieved. Levelled operation has been in use during the first run of the LHC for one of its experiments, LHCb. There are proposals to adopt it also during LHC run 2 for some operational scenarios in view of the HL-LHC era, when luminosity levelling will become a necessity. Several options are available to implement such technique. One possibility is to start collisions with a larger  $\beta^*$  than what could be achieved. The latter is then decreased in a controlled way during the fill. In this way the instantaneous luminosity stays constant for a given period of time, after which the adopted compensation stops being effective, and the natural exponential decay of the luminosity takes place. The duration of luminosity levelling  $t_{lev}$  can be approximately calculated as shown in Eq. 6.12, assuming that the luminosity lifetime is mainly determined by particle burn-off. This assumption is particularly oriented to HL-LHC operation.

$$L_{lev} = L_p e^{-\frac{t_{lev}}{\tau}} \quad (6.12)$$

where  $L_{lev}$  is the chosen value of instantaneous luminosity allowing to limit event pile-up.

### 6.1.5 Model Validation against 2012 Operation

The Monte Carlo model was validated against 2012 operation to quantify the error on the estimated yearly integrated luminosity (90). Distributions were produced for the integrated luminosity, stable beams, fault and turnaround times over 1000 cycles of the model to verify the correspondence of all relevant quantities related to machine availability to observations. Results are presented in Fig. 6.12.

Table 6.5 shows the comparison of 2012 yearly figures with the average of the corresponding simulated quantities. The model error for the prediction of integrated luminosity amounts to 1%, which is acceptable for the purpose of this work, whose focus is on identifying areas and systems for significant performance improvements and major limitations for operation.

## 6. AVAILABILITY-DRIVEN OPTIMIZATION OF ACCELERATOR PERFORMANCE

---

**Figure 6.12:** Model statistics of relevant simulated quantities for quantifying the impact of availability on integrated luminosity. Results are relative to 1000 cycles of the Monte Carlo model.

## 6.2 LHC performance for Post-LS1 operation

---

Quantity	Measured	Simulation (Average)	Error (%)
Integrated Luminosity [ $fb^{-1}$ ]	23.27	23.04	0.9
Total Fault Time [h]	1418	1410	0.6
Total Turnaround Time [h]	1612	1613	<0.1
Total Stable Beams Time [h]	1794	1791	0.2
Number of fills to Stable Bemas	295	295	<0.1
Number of fills with no faults	90	90	<0.1

**Table 6.5:** Comparison of 2012 observations with corresponding simulated quantities through the Monte Carlo model of LHC operation.

## 6.2 LHC performance for Post-LS1 operation

### 6.2.1 Impact of Future Operational Scenarios

In 2012 the cryogenic system had the largest contribution to LHC downtime, though the absolute number of failure events has been lower than for other systems. Cryogenic stops have long recovery times, ranging from some hours to few days, with an average of 9.6 h. After LS1 the resistive heat load as well as the synchrotron radiation levels will increase significantly due to the higher energy (6.5 TeV), resulting in an operating point closer to design values. Failures of rotating machinery will have a higher impact on availability. Furthermore it will take longer to recover operating conditions after magnet quenches. Mitigation strategies for the cryogenic system consist in major overhauls of rotating machinery, reinforcement of magnetic bearing controllers in the cold compressors against electro-magnetic coupling and implementation of mitigations against SEUs in point 2, 4 and 6 of the LHC.

A significant contribution to LHC downtime is caused by failures of the power converters. A total of about 1700 power converters are used to feed LHC magnets. Recovery times are shorter than for the cryogenic system (the average fault time amounts to 1.6 h), but failures are more frequent. A power converter for the LHC is composed of two main blocks: a voltage source and a Function Generator Controller (FGC). The voltage source is the main power part of the power converter. The task of the voltage source is to receive the mains power and convert it to a suitable DC output voltage, controlled by a reference input. The FGC executes a digital regulation loop, comparing

## 6. AVAILABILITY-DRIVEN OPTIMIZATION OF ACCELERATOR PERFORMANCE

---

the reference value and the feedback on current measurements to calculate the appropriate control value for the voltage source periodically. Known failure modes have been addressed during LS1 with dedicated solutions. In particular voltage sources are being consolidated to be more reliable than during run 1. A project for the replacement of the current power converter controllers (FGC2) was launched with the scope of having a radiation-tolerant system in the future (FGClite (93)). This system will not be in place for the restart of the LHC in 2015, but will be deployed before the second year of run 2. When first deployed, care must be given to reduce failures caused by infant mortalities of the new system, such that the machine availability will not be affected significantly.

Also the Quench Protection System (QPS) caused in 2012 a high number of relatively short stops (with an average fault time of 2.2 h). These were mainly due to sensitivity of electronic components to radiation in exposed areas and to bad connections leading to spurious triggers of the quench detection electronics and the energy extraction system. A campaign was launched to mitigate such effects: the relocation of electronics in combination with the use of radiation-tolerant electronics should mitigate most of the radiation-induced faults. Cabling will be carefully checked before the restart. In addition a remote-reset functionality has been implemented to mitigate failure due to lost communication with quench detection electronics. These measures should reduce the number of faults and the average fault time.

For all other LHC systems, consolidation of failure modes identified during run 1 has been carried out during the long shutdown 1 (5). In this respect, the philosophy being followed is to first improve safety and then availability. As it is intuitive, the increased number of interlock channels enhances the probability of having spurious dumps. Therefore some of the consolidation measures could potentially reduce availability in order to ensure higher safety. An example is the LHC Beam Dumping System (LBDS) retriggering line via the BIS, which will provide an independent means of triggering a beam dump in case of a complete failure of the LBDS redundant triggering (see 5.2.4). A dedicated study was performed to verify that the introduction of this additional system would not affect availability (80). The study revealed in fact that the overall impact on availability will be negligible. Another example is the implementation of additional interlocking channels in the Software Interlock Systems (SIS), which were not present during run 1. During run 2, the interlock for monitoring of the abort gap

## 6.2 LHC performance for Post-LS1 operation

---

population will ensure a clean abort gap, avoiding large particle losses during the rise time of the LBDS kicker pulse.

Considering beam-related effects and availability, the extrapolation of observed UFOs to 6.5-7 TeV forecasts up to 100 dumps per year after LS1 (45). The analysis of UFO events in the first LHC run reveals that losses generated by dust particles can be observed in the machine at particular locations (e.g. near the injection kicker magnets). Such losses may not be above the BLM thresholds and therefore do not necessarily cause a beam dump. The increasing beam energy will nevertheless strongly enhance beam losses produced by dust particles. UFOs have shown a clear conditioning trend during LHC run 1, however deconditioning is expected following the consolidations in the machine vacuum segments. Relocation of BLMs to catch UFO events will ensure maintaining a high level of protection while allowing to increase BLM thresholds at the quadrupole locations (27). The redefinition of BLM thresholds, according to recent studies on quench limits, should allow the right balance between detection of dangerous events versus unnecessary LHC stops to be found. UFOs are an example of a failure mode of the machine which was not taken into account in the design phase, as it was believed that similar effects would not be observed in hadron machines.

### 6.2.2 Integrated Luminosity Predictions and Sensitivity Analyses

The Monte Carlo model was used to predict the achievable integrated luminosity during LHC run 2 and 3, taking into account mitigations and operational constraints described in 6.2.1.

**Predictions for 2012-like availability** The starting point of the analysis is represented by figures from 2012 (see 6.1.1). This assumption was made in the attempt to describe stable and reproducible LHC operation. The presented results for run 2 are therefore to be intended for nominal LHC operation, starting from 2016. Full exploitation of 25 ns bunch spacing beams will be the primary goal of the 2015 run. Standard beams, as well as high brightness beams, obtained by Batch Compression bunch Merging and Splitting (BCMS (94)), could be used. The key parameters for these two options are summarized in Table 6.6. For the BCMS option, the possibility of reliable operation with 25 ns bunch spacing still has to be validated in 2015. In this case, it is assumed to exploit luminosity levelling (92).

## 6. AVAILABILITY-DRIVEN OPTIMIZATION OF ACCELERATOR PERFORMANCE

---

Beam	$\beta^*$	Leveled Luminosity ( $10^{34}[cm^{-2}s^{-1}]$ )	Peak Luminosity ( $10^{34}[cm^{-2}s^{-1}]$ )
Standard	0.5	-	1.2
BCMS	0.4	1.54	2.2

**Table 6.6:** Beam parameters for LHC run 2.

The first step for luminosity predictions is to directly extend the distributions of stable beams and fault time observed in 2012 to post-LS1 operation. This implies in first approximation having the same availability as in 2012. The increased energy has an influence on the magnet current ramps, which will intrinsically be longer than in the past, resulting in an estimated average turnaround time of 6.2 h instead of 5.5 h. The same ratio of low-intensity to high-intensity fills as 2012 is taken, to reproduce a realistic intensity ramp-up. Results for this scenario are presented in Figs 6.13 and 6.14, for both nominal 25 ns beams and BCMS.

**Figure 6.13:** Distribution of integrated luminosity for standard 25 ns beams during LHC run 2.

The plots show that assuming 2012 system availability and 160 days of proton-proton operation the target for yearly luminosity production of  $28 fb^{-1}$  for standard beams and  $53 fb^{-1}$  for the BCMS option can be achieved.

The analysis has then been extended to standard operation with Linac4 (run 3),

## 6.2 LHC performance for Post-LS1 operation

**Figure 6.14:** Distribution of integrated luminosity for BCMS beams during LHC run 2.

assuming the beam parameters shown in Table 6.7. The predicted integrated luminosity during run 3 amounts to  $53 \text{ fb}^{-1}$  (Fig. 6.15). It can be observed that operation with Linac4 and with BCMS beams yields very similar outcomes in terms of luminosity production, as reported in (95).

Beam	$\beta^*$	Leveled Luminosity ( $10^{34}[\text{cm}^{-2}\text{s}^{-1}]$ )	Peak Luminosity ( $10^{34}[\text{cm}^{-2}\text{s}^{-1}]$ )
Standard Linac4	0.4	1.65	2.1

**Table 6.7:** Beam parameters for LHC run 3 with Linac4 operation.

**Extension of 2012 figures for future LHC operation** The distributions derived in 2012 are a good starting point for the analysis of future scenarios. An extension of these distributions is considered to account for the efforts invested in the mitigation of failure modes affecting LHC run 1. Furthermore, the impact of new beam parameters on previously observed phenomena, as e.g. UFOs and R2E, has to be considered.

The distribution of R2E-induced downtime was shown in Fig. 6.7 for 2012. Considering LS1 mitigations and future system upgrades, the number of R2E-induced faults

## 6. AVAILABILITY-DRIVEN OPTIMIZATION OF ACCELERATOR PERFORMANCE

---

**Figure 6.15:** Distribution of integrated luminosity for standard operation with Linac4 beams during LHC run 3.

has been extrapolated for the future LHC runs to estimate the resulting gain in terms of integrated luminosity. The extrapolation is based on estimated radiation levels in the different underground areas of the LHC tunnel. These include both the expected hadron fluence and dose (see C.1). Estimates of radiation levels have been made for 2015, the second part of run 2 (2016-2018), run 3 (2020-2022) and HL-LHC (from 2025). The extrapolation of the number of dumps caused by SEU was carried out accordingly. A linear scaling of the number of SEU with the hadron fluence is assumed, according to (96).

- Beginning of run 2 (2015): the higher radiation levels due to the increased energy (6.5 TeV) will be approximately compensated by the expected lower level of luminosity production. 2012-like radiation levels are expected.
- Second part of run 2 (2016-2018): increased radiation levels due to the higher luminosity production. The introduction of the FGClite will ensure the full mitigation of R2E effects on the power converter controls.
- Run3 and HL-LHC: radiation levels will further increase and it is assumed that no further upgrades or mitigations will be performed. This is a conservative assumption.

## 6.2 LHC performance for Post-LS1 operation

---

Table 6.8 summarizes the results of these considerations. The impact of cumulative effects due to radiation dose will be addressed later in the paragraph.

	Expected number of dumps per year	Total Downtime [h]
<b>2015</b>	10	44
<b>Run 2</b>	9	35
<b>Run 3</b>	15	55
<b>HL-LHC</b>	25	84

**Table 6.8:** Extrapolation of dumps caused by SEU in the future LHC runs.

Failure modes leading to the longest downtimes were mitigated already in view of run 2. As a consequence, the average fault time consistently decreases in the three phases. The total downtime increases over time, as expected due to increased radiation levels. A quantitative analysis has been carried out to evaluate the impact of R2E mitigations on the integrated luminosity for run 2 and 3:

- Second part of run 2 (2016-2018): R2E mitigations determine a significant reduction of the machine failure rate with respect to 2012 operation (MFR = 53 %). The R2E fault time distribution was adjusted to account for mitigation measures.
- Run3: the machine failure rate will only slightly increase due to R2E effects, excluding the occurrence of long term effects like ageing due to accumulated dose on exposed equipment (MFR = 55 %).
- HL-LHC: the machine failure rate will increase mainly due to the higher luminosity production (MFR = 60 %).

Luminosity predictions were made with the Monte Carlo model for the last three scenarios, according to the newly defined machine failure rates and fault time distributions. Results for run 2 and run 3 are shown in Figs 6.16, 6.17, 6.18.

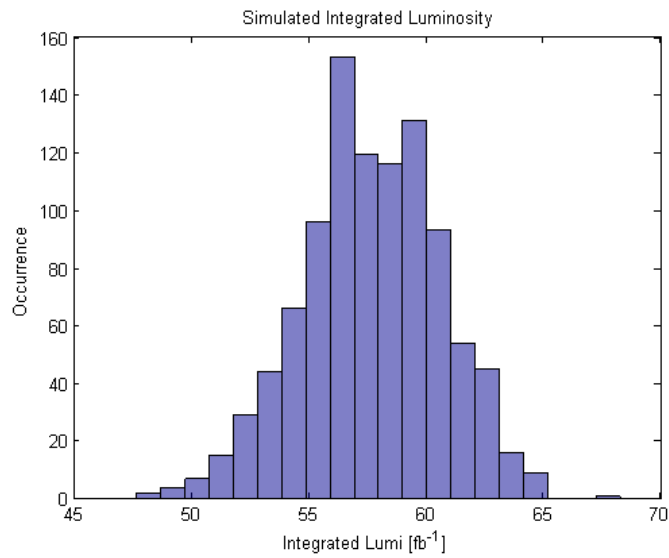

The predicted luminosity in the case of standard beams and BCMS is 30 and 57  $fb^{-1}$ , respectively. The predicted luminosity for standard operation with Linac4 is 58  $fb^{-1}$ , considering the increased failure rate compared to run 2 (55 %). A gain of about 10 % of integrated luminosity can be expected comparing these results with

## 6. AVAILABILITY-DRIVEN OPTIMIZATION OF ACCELERATOR PERFORMANCE

---

**Figure 6.16:** Distribution of integrated luminosity for standard 25 ns beams during LHC run 2, considering the effect of R2E mitigations.

**Figure 6.17:** Distribution of integrated luminosity for BCMS beams during LHC run 2, considering the effect of R2E mitigations.

## 6.2 LHC performance for Post-LS1 operation

**Figure 6.18:** Distribution of integrated luminosity for standard operation with Linac4 beams during LHC run 3, considering the effect of R2E mitigations.

the ones obtained using 2012-like distributions. A direct comparison on luminosity production for the different scenarios can be found in Table 6.9.

	<b>Integrated Luminosity (2012 availability)</b>	<b>Integrated Luminosity (R2E mitigations)</b>
<b>Run 2 (std)</b>	28 $fb^{-1}$	30 $fb^{-1}$
<b>Run 2 (BCMS)</b>	53 $fb^{-1}$	57 $fb^{-1}$
<b>Run 3 (std + Linac4)</b>	53 $fb^{-1}$	58 $fb^{-1}$

**Table 6.9:** Extrapolation of dumps caused by SEU in the future LHC runs.

The predicted gain obtained from R2E mitigations is considered to be a conservative estimate. R2E effects are more likely to be observed in the early part of stable beams, when higher peak luminosity leads to higher radiation, causing a more significant loss of luminosity. Considering this aspect, R2E mitigations could lead to an additional gain in terms of luminosity production.

In addition to this study, a qualitative analysis of the impact of fault frequency and fault time on integrated luminosity can be carried out with the Monte Carlo model. This allows reproducing qualitatively the results obtained with the detailed R2E fault data analysis and making extrapolations for other availability-relevant scenarios. A

## 6. AVAILABILITY-DRIVEN OPTIMIZATION OF ACCELERATOR PERFORMANCE

**Figure 6.19:** Sensitivity analysis of the integrated luminosity to average fault time and machine failure rate for standard 25 ns beams during LHC run 2.

sensitivity analysis was performed with respect to the average fault time and machine failure rate. Simulations were carried out for a given set of input parameters. The averages of the distributions resulting from 1000 cycles of the model are plotted on a common chart. Results obtained with such technique are shown for standards beams (Fig. 6.19), BCMS (Fig. 6.20) and standard beams with Linac4 (Fig. 6.21).

Considering the impact of R2E faults on integrated luminosity for standard operation during run 2 as an example, it can be observed in Fig. 6.19 that a reduction of the machine failure rate to 53 % yields 30-32  $fb^{-1}$ , compared to 2012 availability, yielding instead 26-28  $fb^{-1}$ . This is in agreement with results summarized in Table 6.9. This approach was therefore followed to study different LHC operational scenarios.

It is expected that UFOs will play a significant role with respect to the MFR for operation with increased energy and 25 ns bunch spacing. Latest extrapolations on UFOs lead to the assumption that a MFR of 80 % should be expected in the future (without considering the effect of R2E mitigations). At the same time, it is known that under the assumption that each UFO event is caught by the BLM system, the associated fault time amounts only to few seconds. This leads to a reduction of the average fault time. These considerations can be translated on the chart and the effect can be observed in Fig. 6.19. The sensitivity analysis shows then that a reduction of

## 6.2 LHC performance for Post-LS1 operation

**Figure 6.20:** Sensitivity analysis of the integrated luminosity to average fault time and machine failure rate for BCMS beams during LHC run 2.

**Figure 6.21:** Sensitivity analysis of the integrated luminosity to average fault time and machine failure rate for standard beams with Linac4 during LHC run 3.

## 6. AVAILABILITY-DRIVEN OPTIMIZATION OF ACCELERATOR PERFORMANCE

---

the integrated luminosity of up to 10 % can be expected due to the increased UFO rate.

A realistic scenario for future LHC operation must account for both the reduced impact of SEUs and increased number of UFO events. Considering these two factors, a 2012-like availability could be achieved during run 2. The challenges to be faced have been discussed in 6.2.1.

During run 3, the effects of ageing due to cumulative radiation effects could start to be observed in the machine. If the maximum tolerated dose would be reached for a given equipment, then several failures have to be expected in a very short time. This can be interpreted in the sensitivity analysis as a sudden increase of the machine failure rate (e.g. by 10 %). Fig. 6.21 shows a consequent reduction of about 10 % of the integrated luminosity, assuming no major impact on the average fault time. This is reasonable in case of failures regarding electronic systems for which a sufficient number of spare parts is available.

### 6.2.3 Integrated Luminosity Optimization through Availability

The limitations imposed by the event pile-up in the experiments justify the efforts invested for improving system availability. In this section it will be shown that given a certain level of availability, a further gain in terms of integrated luminosity can be achieved by optimizing the time in stable beams. This aspect is particularly relevant when dealing with leveled operation. The exploitation of luminosity levelling ensures that luminosity production is still effective even after several hours in stable beams. It is intuitive that in this case luminosity production would benefit from longer stable beams. Luminosity optimization based on measured availability and time in stable beams becomes then a relevant aspect for improving the performance.

The ideal time to be spent in stable beams can be found by applying a constrained nonlinear optimization algorithm to the integrated luminosity. Such an algorithm has been developed in MATLAB (51) to determine the optimum number of fills and stable beams. The algorithm takes as inputs the average turnaround time, the average fault time and the machine failure rate. As beam parameters the peak luminosity and the luminosity lifetime are considered. Constraints are set to model the desired dependencies among these variables and the parameters to optimize.

## 6.2 LHC performance for Post-LS1 operation

---

Six 'abstract scenarios' with different assumptions for the input parameters were defined and the maximum achievable integrated luminosity calculated, assuming BCMS as an operational baseline and 160 days of operation:

1. Optimized luminosity without machine faults, i.e. the maximum achievable luminosity; (machine failure rate = 0 %, turnaround time = 4 h)
2. Optimized luminosity including external faults, i.e. faults out of CERNs control (e.g. electrical network) (machine failure rate = 0.08 %, turnaround time = 4 h, fault time = 2.7 h)
3. Optimized luminosity with figures from 2012 (machine failure rate = 70 %, turnaround time = 6.2 h, fault time = 7 h)
4. Optimized luminosity in case all machine faults would require no access in the tunnel to be solved (machine failure rate = 70 %, turnaround time = 6.2 h, fault time = 1 h)
5. Optimized luminosity in case all machine faults would require one access (machine failure rate = 70 %, turnaround time = 6.2 h, fault time = 4 h)
6. Optimized luminosity in case all machine faults would require major interventions (machine failure rate = 70 %, turnaround time = 6.2 h, fault time = 12 h)

The results for these six scenarios are summarized in Table 6.10. It shows the maximum achievable integrated luminosity for optimized stable beams lengths. In all scenarios it is assumed to have 2.1 h of levelling, followed by the natural exponential decay of the luminosity. The optimization is only applied to fills which are intentionally aborted by operators. These results exhibit purely theoretical values, as such optimization can be performed only after measuring fault distributions that occurred during the run. Every time a fault occurs during operation, the optimum working point in terms of ideal stable beams length changes. The latter becomes longer with increasing fault times, as could be assumed intuitively.

Nevertheless, the optimization algorithm could be used to assist daily LHC operation. It could provide to LHC operators the necessary information to dynamically optimize luminosity by acting on the duration of stable beams. In order to verify

## 6. AVAILABILITY-DRIVEN OPTIMIZATION OF ACCELERATOR PERFORMANCE

---

Scenario	Stable beams [h]	Number of fills (EOF / Failures)	Integrated Luminosity (BCMS)
1	5.5	405 / 0	100.5 [ $fb^{-1}$ ]
2	5.6	364 / 32	98.3 [ $fb^{-1}$ ]
3	8.0	69 / 160	56.4 [ $fb^{-1}$ ]
4	6.8	95 / 221	75.9 [ $fb^{-1}$ ]
5	7.5	80 / 186	64.5 [ $fb^{-1}$ ]
6	8.4	63 / 148	52.3 [ $fb^{-1}$ ]

**Table 6.10:** Optimized integrated luminosity for different failure scenarios.

and quantify the effectiveness of the optimization approach, the Monte Carlo model was used to generate a yearly timeline of LHC operation. After every simulated beam dump, the optimization algorithm is used to calculate the optimum stable beams length. The latter is then assumed as the maximum allowed duration of the next fill. The optimization is nevertheless only applied to the fraction of fills which are intentionally aborted by operators (100 - MFR %). The procedure is iterated in such a way that the working point is modified after each dump until the end of the scheduled run-time.

An example of simulated LHC operation is shown in Fig. 6.22, assuming BCMS beams. In the plot 400 h of LHC run are shown on the x-axis, common to all plots.

- The first plot (green) shows the evolution of the delivered integrated luminosity over time.
- The second plot (red) shows the expected delivered integrated luminosity. This is the sum of the delivered luminosity and the optimized luminosity still to be delivered in the remaining run time, calculated with the algorithm.
- The third plot (blue) shows the optimum number of fills, calculated with the algorithm.
- The fourth plot (light blue) shows the optimum number time in stable beams, calculated with the algorithm.
- The fifth plot (purple) shows the average fault time per LHC fill, randomly generated.

## 6.2 LHC performance for Post-LS1 operation

**Figure 6.22:** Simulated timeline of LHC operation with BCMS beams.

## 6. AVAILABILITY-DRIVEN OPTIMIZATION OF ACCELERATOR PERFORMANCE

---

After 400 h, 6  $fb^{-1}$  have already been delivered (green). The prediction for the optimized luminosity (red) yields 65  $fb^{-1}$  to be produced in total in 160 days, if 180 stable beams could be reached (blue) and aiming to dump the beam after 13-14 h (light blue) for optimization. The optimum number of fills (blue) tends to zero, as it is function of the remaining run time. The optimum time in stable beams consistently increases with the average fault time, as intuitively longer stable beams are desirable with longer fault times. This can be observed in particular at the beginning of the run, when the fault time amounts to 3 h, leading to 15 h of ideal stable beams duration. The next failure brings the average fault time to 5 h, which increases the optimum time in stable beams and significantly worsens the expected luminosity production (about 50  $fb^{-1}$ ).

A quantification of the gain that could be achieved by performing online optimization of stable beams during LHC operation has been carried out.

1. Considering 2012-like availability and BCMS beams, an integrated luminosity of 53  $fb^{-1}$  was predicted (Table 6.9). Applying the optimization for 2012 availability allows reaching 55  $fb^{-1}$ , yielding a gain of about 3.5 % of integrated luminosity.
2. Considering a machine failure rate of 53 % (i.e. is taking into account R2E mitigations), an integrated luminosity of 57  $fb^{-1}$  was predicted (Table 6.9). Applying the optimization allows reaching 62  $fb^{-1}$ , yielding a gain of about 9 % of integrated luminosity.

As expected, the effectiveness of the optimization is enhanced for a lower machine failure rate, as this implies that the number of fills to be optimized by the operators increases.

### 6.3 LHC performance in the High-Luminosity era

#### 6.3.1 Impact of Future Operational Scenarios

The CERN HL-LHC era will start in 2025, setting unprecedented targets in terms of integrated luminosity and availability for a circular collider. The HL-LHC goal is to provide to the LHC experiments 250-300  $fb^{-1}$  per year. For ultimate HL-LHC beam

### 6.3 LHC performance in the High-Luminosity era

---

parameters, the integrated luminosity could go up to  $400 \text{ fb}^{-1}$  per year. A major series of upgrades is foreseen in order to achieve this challenging target.

Firstly, in order to overcome the limits imposed by event pile-up, the experiments will be substantially upgraded. The maximum pile-up of the detectors during run 1 has been set from design to 25. Upgrades will ensure an improvement up to a pile-up of 140 (97) (98). This will be achieved by improved performance of both particle detectors and read-out electronics.

From the accelerator perspective, the superconducting triplets close to the main experiments will be replaced by  $Nb_3Sn$  triplets. The triplets currently in use in the LHC were designed for a total integrated dose of  $300 \text{ fb}^{-1}$ , which will be reached by 2023.

Advanced collimator designs and materials (e.g. Molybdenum-Graphite) are under study to cope with the increased power stored in the beam halo.

An innovative concept will be used for improving beam collisions. The beams are normally put into collisions introducing a deflection in their orbit by a certain angle, called the crossing angle. This implies that due to the geometry of the collisions, the beams are not fully overlapping at the interaction points. A so-called geometric factor is used in the calculation of luminosity to account for this effect. The crab cavities (17) are capable of tilting the beam close to the interaction point to ensure an optimized overlap of colliding bunches. The original beam configuration is then restored to match the LHC lattice.

Reaching increased luminosity will have a significant impact on the thermal load on the superconducting magnets at the interaction points. New cryo-plants will therefore be installed to decouple such magnets from the rest of the sector. Similarly, the superconducting cavities in the LHC point 4 will also be decoupled from the sector cryogenic system.

The introduction of new systems and particularly of the crab cavities may have strong implications on the MPS. New strategies to cope with new possible failure modes are already under discussion (99) to keep the same level of safety of the current LHC. On one hand additional monitoring and protection for the new systems is needed to prevent major consequences in case of failures (preserving availability). On the other hand the introduction of additional systems and their monitoring implies the possibility of introducing new sources of false dumps, with a potential impact on the total downtime

## 6. AVAILABILITY-DRIVEN OPTIMIZATION OF ACCELERATOR PERFORMANCE

---

(affecting availability). Managing new systems and the related protection is the main concern in view of HL-LHC also in terms of availability.

Beam performance of HL-LHC will also play a significant role with respect to availability. Luminosity leveling, aiming at the increase of integrated luminosity by the extension of the time in collisions, will be the baseline for HL-LHC operation. Leveling is possible thanks to high beam intensities and will lead to higher integrated luminosity than in the past, both factors that directly affect radiation levels in the LHC tunnel. It has been estimated that in specific areas a factor 20 higher hadron fluence should be expected for ultimate HL-LHC parameters, leading to 25-40 dumps per year due to R2E, in case no additional mitigations will be deployed after the Long Shutdown 3 (6.8). For example, it is already under consideration that certain power converters could be relocated and moved from the tunnel to the surface areas to prevent R2E-induced faults. This entails the necessity of designing superconducting links from the power converters to the magnets (19).

The aforementioned factors imply that increasing the availability for physics will be challenging, but crucial for reaching the HL-LHC goals. As shown in this thesis, this can only be achieved by the combined reduction of the fault frequency and time. For some systems the fault time is imposed by physical constraints. For the cryogenic system for example, the recovery from a quench at 7 TeV takes around 12 h. Electronic systems have instead significant margins for improvement for what regards the fault time, for example by the enhancement of remote diagnostics and reset capabilities in case of false dumps.

For the reduction of the fault frequency, efforts will be required for the design of even more reliable systems. Considering R2E failures for example, effective measures as relocation of equipment, shielding and use of radiation tolerant components have been already applied during LS1 (100) and will have to be enforced in the future. As shown in 5.2, detailed studies on advanced architectures for the next generation of interlock systems would allow significant improvements in terms of availability. Obsolescence of components, especially for electronic systems designed in 2005 and before, may become an issue when approaching the HL-LHC era. Management of spare parts to cope with the onset of component wear-out should be carefully evaluated to ensure a sufficient stock of spares parts while still commercially available.

### 6.3 LHC performance in the High-Luminosity era

A strategy is needed to define areas for improvements and necessary interventions, to coordinate efforts and possibly identify common areas for new developments. Requirements for the design of new systems should be derived based on the current understanding of the LHC. The developed Monte Carlo model is a powerful tool to provide guidelines and identify individual system requirements to achieve the challenging HL-LHC goals. The LHC run 2 data will represent an important chance of validating the developed models.

#### 6.3.2 Integrated Luminosity Predictions and Sensitivity Analyses

Luminosity predictions as a function of availability have been performed for HL-LHC with the use of the Monte Carlo model presented in 6.1.4.

**Predictions for 2012-like availability** As done in 6.2.2 for LHC run 2 and 3, 2012 availability figures are taken as a reference. Table 6.11 summarizes the adopted beam parameters for the simulations.

Beam	Luminosity Lifetime [h]	Leveled Luminosity ( $10^{34}[cm^{-2}s^{-1}]$ )	Peak Luminosity ( $10^{34}[cm^{-2}s^{-1}]$ )
<b>Standard HL-LHC</b>	4.7	5	21.9

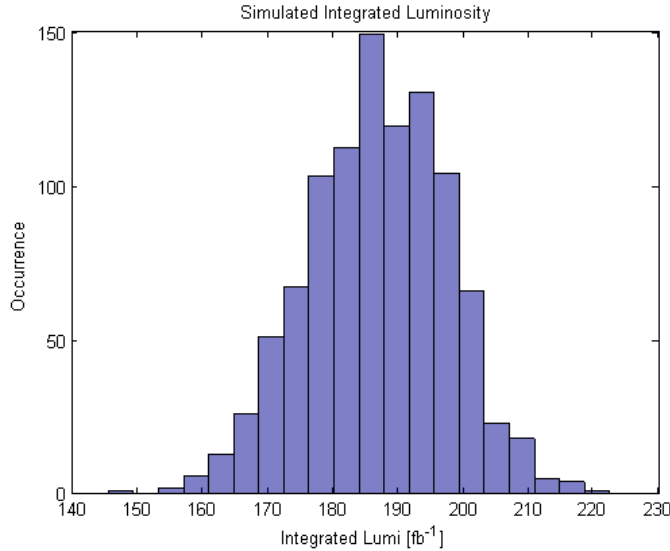

**Table 6.11:** Beam parameters for HL-LHC operation.

Results for HL-LHC operation are shown in Fig. 6.23, assuming 160 days of operation. An integrated luminosity of  $186 fb^{-1}$  could potentially be achieved. This value has to be compared to the target of 250-300  $fb^{-1}$  of the HL-LHC project. A significant improvement in terms of availability is needed to reach HL-LHC goals.

**Extension of 2012 figures to HL-LHC operation** For a comprehensive model of HL-LHC luminosity production, both increased beam and machine performance and new system upgrades need to be taken into account. Table 6.8 shows that 25 R2E-induced failures have to be expected per year in the HL-LHC era, assuming no further mitigations after the ones deployed during the long shutdown 1. This translates in a machine failure rate of about 60 %, mainly driven by the increased luminosity

## 6. AVAILABILITY-DRIVEN OPTIMIZATION OF ACCELERATOR PERFORMANCE

---

**Figure 6.23:** Distribution of produced integrated luminosity for HL-LHC, assuming 2012 availability.

production. Fig. 6.24 shows the impact of this scenario on the integrated luminosity. An integrated luminosity of  $200 \text{ fb}^{-1}$  could be achieved considering R2E mitigations.

	<b>Integrated Luminosity (2012 availability)</b>	<b>Integrated Luminosity (R2E mitigations)</b>
<b>HL-LHC</b>	$186 \text{ fb}^{-1}$	$200 \text{ fb}^{-1}$

**Table 6.12:** Extrapolation of dumps caused by SEU in the future LHC runs.

As explained in 6.3.1, R2E effects are nevertheless not expected to be the main limitation to HL-LHC availability. To account for further factors affecting availability, a sensitivity analysis to the average fault time and machine failure rate has been carried out. The results are shown in Fig. 6.25. The plot shows that a reduction of the machine failure rate to 50 % and a significant reduction of the average fault time (about a factor 2) are necessary to achieve the target of  $250 \text{ fb}^{-1}$ . This sensitivity analysis can be used to guide the design of new systems, indicating the maximum acceptable number of dumps per systems that should be envisaged for HL-LHC.

As an example, the sensitivity analysis allowed quantifying the maximum number of R2E-induced dumps that could be accepted during HL-LHC. Assuming that a reduction

### 6.3 LHC performance in the High-Luminosity era

**Figure 6.24:** Distribution of produced integrated luminosity for HL-LHC, with R2E mitigations deployed during the long shutdown 1.

	R2E dumps (2012)	R2E downtime (2012)	Target yearly R2E dumps (HL-LHC)	Target yearly R2E downtime (HL-LHC)
<b>QPS</b>	31	80 h	9	32 h
<b>PC</b>	14	60 h	4	14 h
<b>Cryogenics</b>	4	70 h	1	3.5 h
<b>Vacuum</b>	4	20 h	1	3.5 h
<b>Other</b>	3	30 h	1	3.5 h

**Table 6.13:** Extrapolation of acceptable R2E failure budget per system in the HL-LHC era.

## 6. AVAILABILITY-DRIVEN OPTIMIZATION OF ACCELERATOR PERFORMANCE

---

of 5 % of the machine failure rate should be gained through the mitigation of R2E effects, a total of 16 dumps could be accepted. It is assumed to have the same proportion of R2E dumps among systems observed in 2012 and an average fault time of 3.5 h. The resulting acceptable number of dumps per system is shown in Table 6.13.

**Figure 6.25:** Sensitivity analysis of the integrated luminosity to average fault time and machine failure rate for HL-LHC.

Figures presented in Table 6.13 are only sufficient to cope with the exact number of forecasted dumps due to R2E. It is a common design practice for accelerator systems to foresee operational margins with respect to the given requirements. For HL-LHC it will be crucial to define suitable margins to eventually cope with unforeseen failure modes. LHC run 1 has been a significant demonstration of what could be the impact of unforeseen failure modes (e.g. UFOs) and design bottlenecks (e.g. LBDS common mode failure in the front-end units) on operation.

The impact of an unforeseen failure mode on HL-LHC operation and on the integrated luminosity has therefore been quantified (101). It is assumed that the failure mode is due to R2E, but it is not recognized as such, thus no actions are taken to mitigate it. The goal is to observe how this failure affects LHC operation in the different phases of the LHC lifetime (run 2, run 3 and HL-LHC). It is also assumed that such a

### 6.3 LHC performance in the High-Luminosity era

---

failure would be discovered during LHC run 2. The impact on luminosity was derived with the following procedure:

- Considering up to a factor 20 higher hadron fluence for ultimate HL parameters, this failure could translate into 20 failures during HL-LHC operation.
- The downtime due to R2E stops in 2012 ranged from 30 minutes to 30 h.
- A potential of 10 h (20 failures, each 30 min long) to 600 h (20 failures, each 30 h long) of lost time due to this failure is found.
- HL-LHC aims at  $300 \text{ fb}^{-1}$  over 160 days of operation, i.e.  $1.9 \text{ fb}^{-1}$  per day.
- The lost luminosity would be between  $0.8 \text{ fb}^{-1}$  ( $1.9 \text{ fb}^{-1} * 10 \text{ h}$ ) and  $47 \text{ fb}^{-1}$  ( $1.9 \text{ fb}^{-1} * 600 \text{ h}$ ).
- The lost luminosity for an average R2E stop (3.5 h) would amount to  $5.5 \text{ fb}^{-1}$ .

Figures and predictions shown in this paragraph are based on the current knowledge on future system designs and upgrades, and are therefore subject to uncertainties depending on design changes. Nevertheless the model shows that a consistent and coordinated effort to address availability as a key requirement for future operation is vital to reach the challenging goals of the HL-LHC project.

#### 6.3.3 Integrated Luminosity Optimization through Availability

In 6.2.3 the outcome of the application of availability optimization on integrated luminosity was presented for BCMS beams. Similarly, it is interesting to quantify what could be the gain for HL-LHC operation. Fig. 6.26 shows an example of online optimization of stable beams duration for HL-LHC.

After 400 h, about  $35 \text{ fb}^{-1}$  have been produced in the simulation, with a predicted total luminosity production of about  $210 \text{ fb}^{-1}$ . After few hours of run, a long stop occurs (about 1 day) leading to a sudden increase of the average fault time. This results in a drastic reduction of the expected luminosity, from  $300 \text{ fb}^{-1}$  to  $200 \text{ fb}^{-1}$ , having also an effect on the optimum stable beams duration. The latter consistently increases to cope with longer faults.

## 6. AVAILABILITY-DRIVEN OPTIMIZATION OF ACCELERATOR PERFORMANCE

---

**Figure 6.26:** Simulated timeline of HL-LHC operation.

### 6.3 LHC performance in the High-Luminosity era

---

It is expected that optimization of stable beams length for HL-LHC should be even more effective than for the BCMS case, as luminosity leveling could be exploited for up to 6 hours. The Monte-Carlo model in combination with the optimization algorithm was used to quantify the gain that could be obtained by optimizing the time in stable beams.

1. Considering 2012-like availability and BCMS beams, an integrated luminosity of  $186 \text{ fb}^{-1}$  was predicted (Table 6.12). Applying the optimization for 2012 availability allows reaching  $196 \text{ fb}^{-1}$ , yielding a gain of about 5 % of integrated luminosity.
2. Considering a machine failure rate of 60 % (i.e. is taking into account R2E mitigations), an integrated luminosity of  $200 \text{ fb}^{-1}$  was predicted (Table 6.12). Applying the optimization allows reaching  $227 \text{ fb}^{-1}$ , yielding a gain of about 13 % of integrated luminosity.

These results confirm that for longer luminosity leveling times, the optimization of stable beams duration will be even more effective (see 6.2.3 for comparison). Such operational aspect will therefore be one of the important factors to take into account while aiming at  $300 \text{ fb}^{-1}$ . Reaching ideal fill lengths both by tuning the duration of stable beams and reducing the turnaround time will bring a significant increase of the yearly integrated luminosity.

## 6. AVAILABILITY-DRIVEN OPTIMIZATION OF ACCELERATOR PERFORMANCE

---

## 7

# Conclusions and Outlook

Availability is becoming a key figure of merit in the design of particle accelerators. The potential for new discoveries of accelerators depends on both peak beam performance and integrated time for data production for the experiments, i.e. on machine availability. High-power particle accelerators require the presence of Machine Protection Systems (MPS) to prevent damage resulting from the uncontrolled release of energy stored in the beam and in the magnet powering system. The MPS monitor relevant parameters and inhibit accelerator operation in case of detection of dangerous conditions. The huge complexity of systems interfacing with the MPS, as well as that of the MPS itself, can lead to spurious failures, resulting in the interruption of beam operation (false failures). Therefore the MPS on one hand preserve availability by mitigating or anticipating the impact of machine failures, while on the other contribute to decrease availability due to the false detection of dangerous conditions. The priority of the MPS is to protect the accelerator and its assets, therefore the architecture of MPS has to be fail safe. A failure of the MPS must always result in an action bringing the machine to a safe state. At the same time the number of spurious failures has to be minimized. Once having consolidated procedures and reproducible operation, the focus shifts on optimising the availability. The design of MPS should follow a top-down approach in order to identify all possible sources of unsafety. These do not necessarily result from individual system or component failures, but can be produced by unforeseen interactions among software, hardware systems and humans. A top-down approach is more suitable to account for the combination of these elements during the design phase, to derive requirements and constraints for system behaviour. In this thesis a novel

## 7. CONCLUSIONS AND OUTLOOK

---

method to study complex systems (STPA (53)) has been used to derive availability requirements for a linear accelerator, Linac4, currently under construction at CERN. The advantage of this method over traditional hazard analyses relies on the possibility of addressing different aspects of safety-driven design with a single procedure. The thesis shows that the possible sources of un-availability during accelerator operation derive from very different causal factors. As an example, unavailability can be due to a malfunction of accelerator equipment, as well as to an unnecessary beam abort triggered in the control room by an inexperienced operator. A complete analysis of such causal factors was carried out and will allow for availability optimization during operation.

Linac4 will be the first element of the CERN's injector complex, starting from 2019. All accelerators will rely on beams provided by Linac4, therefore high availability is the crucial requirement to be addressed. The definition of the Linac4 MPS architecture has been carried out taking into account the outcomes of the STPA study. The thesis describes in detail the architecture of the Linac4 Beam Interlock System (BIS), based on a so-called tree structure. Equipment protection is ensured by diverse redundancy of the BIS actuators, which stop the beam in case a failure is detected. High availability is instead enhanced by a dedicated system, the so-called External Conditions, which allow to dynamically optimize the beam delivery to different destinations. If one destination is not available but is supposed to receive beam from Linac4 in a given cycle, then another available destination is calculated and the corresponding cycle executed instead. This ensures maximizing the exploitation of all destinations.

Considering the similarities in the layout, but also the significant differences of the beam parameters, the interlocking strategy for the ESS is also discussed in the thesis. ESS is a user-oriented facility with strict requirements in terms of availability. User experiments can perform valuable measurements only if continuous beam is delivered to the target. The downtime of the facility has therefore to be minimized. This requires highly dependable MPS to prevent any damage-induced downtime caused by a sudden loss of the proton beam (5 MW average power per pulse). Furthermore, the downtime can be reduced by designing systems with enhanced maintainability. Following these principles and the outcome of the Linac4 studies, the preliminary ESS BIS architecture has been derived in the thesis. A particular stress has been given to the choice of a modular design, which allows for commissioning and testing different sections of the

---

accelerator independently. This should ensure high maintainability and faster recovery times.

For future availability-critical facilities, a new generation of interlock systems will need to be designed, based on advanced architectures. A quantitative analysis to assess the achievable levels of machine safety and availability has been carried out for different architectures based on interlock loops. Results were calculated both with an analytical and a Monte Carlo approach. This has ensured at the same time gaining confidence in the results and in the model implementations. The developed models allowed identifying the 2oo3 architecture being the best compromise between safety and availability, both for failure detection and protection. Even assuming error prone voting and considering possible hardware implementations of the 2oo3 voting, the 2oo3 option can be considered the optimal solution. A trade off between costs and architecture performance should nevertheless be considered.

During machine operation new requirements for the MPS often arise to mitigate failure modes that were not considered during the initial design phase. The introduction of new systems, or the modification of existing ones, can have a severe impact on the achieved levels of safety and availability, if not carefully addressed. In the thesis the introduction of an additional layer of protection for the LHC beam dumping system was considered as an example, showing its impact on the overall expected availability of the LHC. A common mode powering failure in the front-end units of the dumping system was discovered during the first run of the LHC. This required the design of an alternative path to ensure the execution of a beam dump even in case of a failure of the front end units. In the latter case, the beam dump would be asynchronous, i.e. not synchronized with the particle-free gap left in the beam for the kicker current rise time. A bottom-up approach was followed for this analysis, given the acquired experience with the system, that allows effectively addressing the impact of individual component failures on LHC operation. The analysis showed that the additional protection layer will not affect LHC availability, being responsible of a negligible increase of the number of asynchronous beam dumps, while significantly decreasing the likelihood of a missed beam dump.

Availability optimization will become crucial for the success of the next generation of high-power circular colliders. In the past, from an experimental perspective, peak beam performance has always been the priority while designing a new machine.

## 7. CONCLUSIONS AND OUTLOOK

---

Given the limitations imposed by the so-called event pile-up at the detectors of particle physics experiments, future colliders will have to be designed to ensure high availability to maximize the number of collisions. In the thesis the LHC and its upgrade to HL-LHC have been taken as an example to demonstrate the importance of availability-driven optimization of accelerator performance. A Monte Carlo model capable of reproducing a realistic timeline of LHC operation was developed to quantify the impact of different availability scenarios on the integrated luminosity during LHC run 2, run 3 and HL-LHC. Potential availability bottlenecks for the future runs have been identified, as e.g. UFOs (Unidentified Falling Objects) and Single Event Upsets (SEUs) caused by radiation to electronics. The impact of such failure modes on integrated luminosity was calculated. It was estimated that the occurrence of failures impacting on machine operation costs on average 5.5 hours (the so-called turnaround time) of time dedicated to beam collisions. The exploitation of luminosity leveling as a baseline for HL-LHC operation implies that the effective duration of stable beams will become longer compared to operation without leveling. This will require even more available systems than what was achieved in the last LHC run. By extrapolating the integrated luminosity based on 2012 availability to HL-LHC, about  $200 \text{ fb}^{-1}$  per year could be produced, lower than the HL-LHC target ( $300 \text{ fb}^{-1}$ ). Availability requirements for individual systems can be deduced based on the outcome of the Monte Carlo model, providing predictions of integrated luminosity as a function of machine failure rate and average fault time. The calculation of the target system availability for future LHC runs has been carried out with respect to radiation-induced faults. Furthermore, given an observed machine failure rate and average fault time, an ideal stable beams length that maximizes the integrated luminosity can be calculated through a non-linear constrained optimization algorithm. The gain of adopting such optimization has been quantified by combining the Monte Carlo model and the algorithm in order to reproduce a realistic timeline of LHC operation. This approach simulates a possible application of the algorithm to assist daily LHC operation. Results show that a gain of up to 15 % in integrated luminosity could be achieved compared to operation with non-optimized stable beams length. This gain is, as intuitive, enhanced for increasing leveling times.

The methodologies applied in this thesis have general validity, as demonstrated by the application of the described studies to different accelerators. Further studies will be performed at CERN in the next years in the field of dependability for MPS. A

---

continuation of the work carried out for Linac4 is required to follow the commissioning steps of the accelerator and the beam interlock system. A partial relaxation of the protection requirements is needed during commissioning to allow for flexible operation and tuning, but this can only be done under certain conditions, i.e. when an acceptable risk can be assumed. As already done for the first commissioning steps, these scenarios must be identified and documented to allow, if needed, masking certain inputs of the beam interlock system.

The design of dependable MPS architectures will be one of the priorities for many future facilities. As mentioned in the thesis, ADS and ITER will be at the cutting edge of the design of a new generation of interlock systems. The results presented in this thesis could give valuable guidelines for such designs. The developed models for interlock loop architectures are flexible and allow extending the availability calculations to an increased number of components, while changing input parameters to reproduce operating conditions of different facilities.

The predictions of LHC luminosity and availability will be compared with run 2 data. The LHC fault tracker will allow a more consistent recording of availability data, that will be used to validate the existing models and possibly improve them. New dependencies could be added in the models, for example considering the impact of beam parameters on the occurrence of particular failure modes (e.g. beam intensity having an effect on single event upsets). New probability distributions of fault times could be used to address the impact of new system designs and upgrades. As done in the thesis for the case of R2E-induced faults, the calculation of the acceptable failure budget per system could be performed to derive system requirements for the HL-LHC upgrade.

Finally, for future machines aiming at higher centre-of-mass energies compared to existing colliders, as the FCC p-p (100 TeV), one of the main challenges will be to identify design solutions to ensure high system availability and maintainability. A top-down description of the accelerator would allow identifying availability bottlenecks and key parameters to be optimized. Given the size of such machines, in the order of 100 km, enhanced diagnostics capabilities and failure prediction strategies will be required to limit interventions on accelerator equipment.

## 7. CONCLUSIONS AND OUTLOOK

---

# Appendix A

## Appendix: Linac4 MPS

### A.1 Linac4 Vacuum Leak

On December 12th 2013 a severe vacuum leak was measured in the Linac4 MEBT line (see 5.1) during beam tests (102). The vacuum leak was caused by a damaged bellow located downstream the first buncher cavity. Fig. A.1 shows a picture of the damaged bellow, following a detailed analysis of the incident.

**Figure A.1:** Linac4: a damaged bellow due to beam losses in the MEBT.

## A. APPENDIX: LINAC4 MPS

---

During machine tests, interlocks monitoring beam losses were intentionally masked to allow the necessary flexibility during operation. The beam current amounted to 12.5 mA, far from the nominal value (40 mA). The beam energy in the MEBT is 3 MeV and the adopted pulse duration for the tests was 300  $\mu$ s (instead of the nominal 400  $\mu$ s) with a repetition rate of 1 Hz. The goal of the test was to measure the beam profile with one of the available wire scanners under a non-nominal configuration of the MEBT quadrupoles (i.e. first quadrupole at nominal current, second and third not powered). With these settings the beam is very focused in the vertical plane and very wide in the horizontal plane. This implies that even small misalignments in the horizontal plane can lead to beam losses. Due to the focusing in the vertical plane, the energy density in the case of beam losses can be significant. The low energy confines the deposition over a very small volume. Furthermore, during days preceding the accident, measurements had shown a misalignment between the RFQ and the MEBT of 1 mm in the horizontal plane. The phase advance was such that losses were exactly located at the lip of the bellow, with a thickness of only 200  $\mu$ m.

Detailed calculations revealed that considering the grazing angle, under the given assumptions, the melting point of stainless steel could be reached after a few pulses (102). Due to the impossibility of detecting beam losses, the beam was continuously lost for several minutes on the bellow before the detection of the vacuum leak.

This recent example shows that even low-energy beams have the potential to cause significant damage to sensitive equipment and consequent downtime due to a necessary repair action.

## A.2 Linac4 BIS Truth Tables

In 5.2.1 the layout of the Linac4 Beam Interlock System (BIS) was presented. The tree-architecture, making use of a daisy chain connection of different controllers, is used for the implementation of the BIS. This configuration is particularly suited for machine protection of linear machines. Master controllers receive inputs from slaves controllers and are interfaced with machine protection actuators. In case of a failure, actuators are activated by master controllers and the beam transmission in the high-energy sections of the Linac is interrupted. Slave controllers gather relevant inputs from machine sensors to detect critical machine failures and give a feedback to master controllers. The number of inputs of each controller is limited to 15, including one input dedicated to the Software Interlock System. In the following, the truth tables of slave devices of the Linac4 BIS are reported (Figs A.2 to A.8). These represent the set of conditions which need to be verified in order to allow beam operation ('1'= OK, '0'= NOK).

## Appendix C

# Appendix: LHC Radiation Levels

### C.1 Extrapolation of radiation levels in LHC underground areas

In Chapter 6, predictions on the expected availability of the LHC during future runs and for the High-Luminosity upgrade are presented. One of the major contributors to the number of dumps during the first LHC run has been radiation to electronics causing single event upsets in exposed equipment in the LHC tunnel and underground areas. An extensive consolidation campaign to cope with such failures has been launched at CERN during the Long-Shutdown 1. Nevertheless it is fundamental to correctly extrapolate the radiation levels in the tunnel for the future LHC runs. This allows designing appropriate measures to withstand the high radiation levels. Such measures range from shielding of the most exposed areas to the use of radiation tolerant components for electronic systems. Radiation levels are mostly a consequence of beam losses near the collimation sections (LHC point 3 and 7) and collision debris from the high-luminosity experiments (LHC point 1 and 5) (96). Fig. C.1 shows a schematic view of the LHC and related underground areas.

Predictions on the number of single event upsets in the future LHC runs presented in Chapter 6 are based on the estimated fluence of High-Energy Hadrons (HEH) reported in Table C.2. The assumption is to have a linear scaling of the total number of observed dumps due to radiation to electronics with the HEH fluence (96). In the table, both HEH fluence and total dose are considered. These are both quantities heavily affecting exposed equipment in the tunnel.

## PERSONAL INFORMATION

## Andrea Apollonio

 438 rue des vertes campagnes, 01170 Gex (France)

 +41 762745905  

 aapollonio@hotmail.it

Sex | Date of birth 26 Nov 1986 | Nationality Italian

## PREFERRED JOB

Electronics engineer, reliability engineer, accelerator physicist

## WORK EXPERIENCE

31 Jul 2009–31 Aug 2009

**Researcher**

NWRA, North West Research Associates, Seattle (United States)

Study of atmospheric phenomena from satellite images

**Business or sector** Professional, scientific and technical activities

1 Jan 2007–31 Jul 2010

**Librarian**

Sala Lettura della Facoltà di Ingegneria  
Via Scarpa, Rome (Italy)

8 Nov 2010–31 Jan 2012

**Technical student**

CERN, Geneva (Switzerland)

Quality analysis of the LHC superconducting busbars

**Business or sector** Professional, scientific and technical activities

1 Apr 2012–Present

**PhD student**

CERN, Geneva (Switzerland)

Reliability and availability studies for particle accelerators and accelerator systems

**Business or sector** Professional, scientific and technical activities

## EDUCATION AND TRAINING

2001–2005

**Diploma in scientific studies**

graduated, 100/100

Liceo Scientifico A. Avogadro  
via Brenta 26, Rome (Italy)

20 Aug 2008–31 Aug 2008

Micron Technology, Avezzano (Italy)  
Semiconductor Physics, CMOS image sensors

12 Dec 2008

**Doctor engineer**

undergraduated  
(110/110 cum laude)

Sapienza Università di Roma, Rome (Italy)

3 Jan 2010–5 Feb 2010

A (excellent)

JUAS (Joint Universities Accelerator School), Archamps (France)  
Accelerator physics

21 Jul 2011

**Doctor engineer**

graduated (110/110 cum laude)

Sapienza Università di Roma, Rome (Italy)

5 Nov 2014–14 Nov 2014

**USPAS certificate of successful participation**

Outstanding

Joint US-CERN-Japan-Russia International Accelerator School, Newport Beach (United States)  
Machine protection for particle accelerators and accelerator systems

PERSONAL SKILLS

Mother tongue(s)

Italian

Other language(s)

	UNDERSTANDING		SPEAKING		WRITING
	Listening	Reading	Spoken interaction	Spoken production	
English	C2	C2	C1	C2	C2
French	C1	C1	B2	B2	B1

Levels: A1/A2: Basic user - B1/B2: Independent user - C1/C2: Proficient user  
[Common European Framework of Reference for Languages](#)

Communication skills

Good ability to adapt to multicultural environments, gained through my work experience abroad

Computer skills

- Good command of Microsoft and Apple operating systems
- Basic knowledge of C programming
- Advanced ability in MATLAB programming
- Good command of Simulink
- Good command of Isograph (Reliability Workbench and Availability Workbench)

Other skills

Sports activities: soccer, swimming, basketball, skiing, volleyball  
Working activities: librarian (scholarship)

Driving licence

B
