Acknowledgements

The present work was carried out at the Institute of Materials Science and Technology of Vienna University of Technology, Austria. The work was part of the nationally funded ALWS (Al-Light Weight Structures) project coordinated by the Leichtmetallkompetenzzentrum (LKR) Ranshofen in Austria.

This research project would not have been possible without the support of many people.

First and foremost, I would like to express my gratitude to my supervisor, Prof. Hans-Peter Degischer, who has supported me throughout my doctoral thesis with his help and guidance. I wish to thank him for his patience, his suggestions and ideas. He was always abundantly helpful and offered invaluable assistance, without him this thesis would not have been written.

Special thanks to W. Fragner and Dr. N. Ulf of LKR Ranshofen for providing the materials and for showing continuous support.

I am grateful to B. Reitingner of RECENDT (Research Center for Non Destructive Testing) Linz in Austria, for the LUS measurements and sharing the literature to understand the problems.

Thanks to Dr. A. Danningner for helping with the pull out tests, as well as her advice and time. I would like to thank H. Knoblich and C. Zaruba for their advice (especially sample preparation) and their assistance in SEM, LOM in the last few years.

S. Zellhofer for his advice on how to use DSC and TMA, and with this, being able to solve all the problems. Big thank you to M. Schöbel for his help with diffraction measurements and for improving my knowledge in this field.

Thanks to R. Bitsche; provision of the design of the demo sample and the test samples as well as discussion about the topic.

In my work I have been blessed with a friendly and cheerful group of colleagues. Big thanks to them for their kind support, collaboration with different tests carried out in this thesis, and also for the motivating and uplifting mood that was kept throughout all working hours. Special thanks to S. Windisch and T. Grünwald for their help and support. It has been pleasure working with each of you.

I owe special, sincere thanks to Dr. M. Schaudé for his support, kind words and especially for his help to allow me to finish my PhD.

I would like to thank all my friends for providing memorable experiences throughout this time and for teaching me how important it is to drop my work once in a while. I am grateful for the wonderful friendships, all the good times, and for each of you who became a part of my life.

Big hug to M. Zawieja for his help with the network problems, software's and for his patience and support as a friend.

Finally, to my best friend (sister) A. Kastner, who always cared to help me overcome setbacks and for being there at all times. Thank you for your friendship, love, support and understanding. For making me laugh and smile, for the amazing moments that you brought into life, and for making Vienna my hometown.

Most importantly, I would like to thank my family, especially my parents for providing me with the opportunity to have come to where I am today. Without them, none of this would have been possible. You have always been my biggest fans and I dearly appreciate that. Thank you for supporting me throughout all my studies, your understanding and endless love.

I deeply appreciate each of you for believing in me.

Kurzfassung

Aluminiumlegierungen sind heutzutage aufgrund ihrer geringen Dichte und ausgezeichneten mechanischen Eigenschaften sehr wichtige Materialien. Aluminium-Silizium-Gußlegierungen werden im Automobilbau, in der Luftfahrt und in vielen Ingenieurbereichen eingesetzt.

Die relativ hohe Schmelztemperatur von Eisenbasislegierungen erlaubt es, dass Eisenkerne verwendet werden, die mit Aluminiumschmelze eingegossen werden. Diese Stahleinsätze werden bei Al-Si-Legierungen durch Kokillenguss, Niederdruck – Kokillenguss und Pressgießen eingebettet. Beim Kokillenguss wurden die Stahleinsätze mit zwei verschiedenen Oberflächen der Stahleinsätze (oxidiert und geätzt) verwendet, wobei die Gussform bei Raumtemperatur und bei hoher Temperatur, 700 und 750°C eingesetzt wird, um die Legierungen, Al (99.8%), AlSi7 und AlSi7Mg0.3 zu vergießen. Im Niederdruck-Kokillenguss wurden zylindrische Einsätze in eine stufenförmige Form eingegossen. Um das Potential von Stahl-Aluminium-Verbund-Guss zu demonstrieren, wurde eine Demo-axial Probe der Dissertation R. Bitsche untersucht.

Der lineare Wärmeausdehnungskoeffizient von Eisen ist nahezu die Hälfte jenes von Aluminium ($\Delta\alpha > 12 \text{ ppm/K}$). Während des Erstarrungsvorganges schwinden Aluminiumlegierungen um zirka 6 vol.%. Dadurch, dass die Dehngrenze dieser Legierungen sehr gering ist, tritt um die Stahleinsätze plastische Verformung auf. Die Differenz im Schwindmaß zwischen Eisen und Aluminium liegt bei rund 1%, die entsprechende lineare Längenänderung übertrifft den elastischen Bereich. Unter der Annahme, dass die Stahleinsätze in der Al-Legierung nach dem Gießen fest eingebettet sind, bewirkt die Schrumpfung bei der Abkühlung unter 275°C elastische Spannungen der Al-Legierung um den Einsatz.

Mit Hilfe von Röntgendiffraktion werden innere Spannungen gemessen. Druckspannungen in der Aluminiummatrix in der Größenordnung von $75 \pm 25 \text{ MPa}$ stammen vom Abschrecken der Al Matrix im eutektischen Umfeld ohne Stahleinsatz. Nahe den Einsätzen erhöhen sich die Tangentialspannungen um ca. 100MPa.

Raster- Elektronen Mikroskopie und Licht Mikroskopie werden zur Gefügecharakterisierung der Proben, insbesondere des Grenzbereiches zwischen Stahl und Aluminium verwendet.

Durch Reaktionen entstehen an den Kontaktstellen zwischen reinem Eisen und reinem Aluminium Al-Fe-Si Phasen. Der Aluminiumguss besteht aus α -Dendriten und Al-Si Eutektikum in den interdendritischen Bereichen. Die Erstarrungsstruktur zeigt hohe Kühlraten in den Oberflächenbereichen nahe der Gussform. Dort ist die Größe dieser Dendriten aufgrund der Erstarrung, welche dort beginnt, viel geringer.

Magnesiumzusätze erlauben Auscheidungshärtung des α -Aluminiums. Die Dehngrenze von Aluminium bei Raumtemperatur liegt bei 50MPa, jene von AlSi12 bei 150MPa und nach Ausscheidungshärtung durch Mg_2Si bei über 200MPa. Die Haftung der Stahleinsätze ist in der Al-Si Legierung, welche Mg enthält, erhöht. Eine Schrumpfungsverformung von 0.3% des Gussteils ergibt eine lokal unterschiedliche plastische Verformung der Bestandteile des Gussgefüges.

In metallografischen Schliffen werden Bindungsfehler zwischen Einlegeteil und Guss sichtbar: Gasporen, Schrumpfungs- und Speisungslunker, Ablösungen und Risse. Durch Laser induzierte Ultraschallmessungen konnten größere Bindungsfehler zwischen dem Stahleinsatz und dem Al-Demo-Guss identifiziert werden.

Neben der Geometrie und der Oberflächenqualität des Stahleinsatzes prägen die Erstarrungsbedingungen die Qualität der Einbettung in einer Al-Gusslegierung. Die Erstarrung sollte entlang des Einlegeteiles beginnen und nicht wieder aufgeschmolzen werden. Für ausreichende Speisung zwischen den Erstarrungsfronten muss gesorgt werden.

Abstract

Aluminium alloys are very important materials because of their low density and excellent mechanical properties. Aluminium silicon casting alloys are essential to the automotive, aerospace and engineering sectors. Aluminium silicon alloys are well established for casting processes; however the silicon forms brittle needle-like particles which reduce impact resistance in cast structures. Inserts of steel or cast iron provide locally increased strength and wear resistance.

The relatively high melting temperature of iron base alloys allows placing iron parts into moulds to be surrounded by the liquid Al-melt, which solidifies embedding the insert. Steel inserts are embedded into Al-Si alloys by gravity casting, by low pressure die casting, and by squeeze casting. Oxidized and etched steel rods with different surfaces are used for the gravity casting. For the gravity casting with steel cube inserts, different thermal conditions are used: mould at RT and high temperature with Al (99.8%), AlSi7 and AlSi7Mg0.3. Insert rings of different heights are used for the low pressure die casting of a step shape. A demo-axial sample has been designed in the thesis by Bitsche to demonstrate the potential of embedding a steel insert into aluminium by squeeze casting of AlSi7Mg0.3.

The linear coefficient of thermal expansion (CTE) of Fe is roughly half of that of Al ($\Delta\text{CTE} > 12\text{ppm/K}$). During solidification, Al-alloys shrink by about 6 vol.%. The yield strength is so low just below the solidification temperature that plastic deformation will occur around an insert. Assuming that elastic stresses can build up below 275°C, the remaining misfit volume between Fe and Al amounts to about 1 vol.%. The corresponding linear length change surpasses the elastic range. The elastic stresses building up depend on the yield strength of the Al alloy at service temperature.

Magnesium additions allow precipitation hardening of the α -Al. The room temperature yield strength of pure Al is around 50MPa, that of the AlSi12 eutectic around 150MPa and after precipitation hardening the alloy by Mg₂Si > 200MPa.

Thus a deformation of 0.3% of the casting causes different degrees of plastic deformation and elastic stresses within the different micro-structural components of the Al alloy around the insert.

The internal stresses in the regions of Al bulk surrounding the insert part are measured by X-ray diffraction. The compressive level of 75 ± 25 MPa in the quenched α -Al Matrix without insert originates from the thermal mismatch with respect to Si. Close to the insert, tangential tensile stresses in Al are identified in the range of 100MPa. The bonding strength increases with the age hardening of the Mg-containing Al-Si alloy embedding the steel inserts with rough surfaces.

Scanning Electron Microscopy and Light Optical Microscopy are used to characterize the microstructure of the samples, particularly the interface between aluminium and steel. Interface reactions produce Al-Fe-Si phases on chemically cleaned steel but not on naturally oxidized. The Al casting consists of α -dendrites and AlSi₁₂ eutectic in the interdendritic regions. Close to the mould, the SDA is much smaller, than in the bulk, when solidification started from the mould owing to the higher cooling rate.

Metallography gives evidence of some cracks, gas entrapment and shrinkage holes detected as well non destructively by Laser Ultrasound. Such defects increase when solidification at the interface is delayed. Summarizing, the geometry of the steel insert or surface preparation and particularly the solidification conditions for the embedding Al-alloy have significant consequence on the interface quality, like reaction bonding, gaps or porosity.

Solidification should begin along the interface, where remelting has to be avoided. Sufficient feeding has to be supplied between the solidification fronts.

Chapter 1

Introduction

Aluminium is an engineering material with only about century of application, but it has become the world's second most used metal after steel. Aluminium is a key component in many aspects of our life – from the buildings we work in to the cars we drive, from the cans we drink to the flights we take. Its combination of very attractive properties - lightweight, stiff, strong, corrosion resistance, recyclable which make it perfectly fine for an almost endless range of applications and an essential part of modern living and which we use every day of our life. Aluminium is the metal of choice for leading designers, architects and engineers, all of whom are looking for a material which combines functionality with forward looking form and design potential at affordable costs.

Aluminium alloys are grouped according to the major alloying elements they contain. The 4XXX group is mainly alloyed with silicon for ease of casting. Aluminium silicon alloys are well established for casting processes. It is possible to produce reliable castings in complex shapes, in which the minimum mechanical properties obtained in poorly fed sections are higher than in castings made from higher strength but lower castability alloys.

Silicon increases the fluidity of the melt, reduces the melting temperature, decreases the contraction associated with solidification and is very cheap as a raw material. Silicon also has a low density (2.34 g cm^{-3}), which may be an advantage in reducing the overall weight of the cast component. Silicon has a very low solubility in aluminium; it segregates in those cast alloys eutectically as virtually pure silicon, which is hard and hence improves the abrasion resistance. The low thermal expansion coefficient is exploited for pistons, the high hardness of the silicon particles for wear resistance. The maximum amount of silicon in cast alloys is of the order of 22-24% Si, but alloys made by powder metallurgy may go as high as 40-50% Si. Increasing silicon content increases strength at the expense of ductility, but this effect is not very marked.

Aluminium has about one-third the density and stiffness of steel. It is easily cast, machined and extruded.

Cast inserts are usually made from cast iron or steel. A metal core needs to be placed in a mould parallel to the parting line of the mould to allow for removing before the casting is ejected from the mould cavity. The shape should also provide easy removal from the casting. Cast-in inserts allow for better surface finish and rapid solidification of the casting, which improve the mechanical properties of the process.

The present work discusses the microstructure of Al-alloys, bonding between steel and aluminium casting prepared by different casting processes. The interface was studied using Light Optical Microscopy (LOM) and Scanning Electron Microscopy (SEM).

The stress analysis has been tried by X-ray and Neutron diffraction. The stresses are determined by the flow behaviour compression test, and the results are described. The aim was to determine in the microstructural influence on the bonding strength.

Chapter 2 describes the state of the art of the cast alloys, as well the general information about aluminium and their applications. Gives the overview of the casting processes with all the defects like pores, shrinkage or cracks, and an effect of solidification rate of the castings.

Description of the methodology describes the geometry of the steel inserts and alloys used for the experimental part, with all the equipments used for the measurements. Chapter 4 presents the results of the work. Measurements results include cast microstructure, hardness value, thermal analysis date, strength and stresses analysis, and laser ultrasound measurements. At the end, discussion of the results and conclusions are shown in Chapter 5 and Chapter 6, respectively.

Chapter 2

State of the art

2.1 Aluminium alloys

2.1.1 General information about aluminium and aluminium alloys

Aluminium (Al) is the most abundant metallic element in the Earth [1] with its application ranging from transportation and packing to construction, infrastructure and aerospace.

Aluminium and its alloys offer an extremely wide range of capability and applicability, with a unique combination of advantages that make it the material of choice for numerous products and markets. Aluminium takes second in production weight behind steel [2].

The main properties which make aluminium a valuable material are:

- Low density, has only one-third of the mass density of steel
- Good conductor of electricity and heat
- Corrosion resistance, the natural aluminium oxide coating acts as an effective barrier to attack
- Non-magnetic, which makes the material useful in electronic industries
- High reflectivity and therefore finds many decorative uses
- Keeps its toughness down to very low temperatures, without becoming brittle like carbon steels
- No-toxic, which made aluminium of use in food and packing industries
- Malleable, which helps for manufacturing and shaping processes
- Recyclable, offering special secondary alloys.

Due to this unique combination of properties, the variety of applications of aluminium continues to increase [3]. It is essential in our daily lives. We can not fly, go by high speed train, high performance car or fast ferry without it. We can not get heat and light into our homes, offices without it. We depend on it to preserve our food, our medicine and to provide electronic components for our computers.

Aluminium alloys are alloys in which aluminium is the predominant metal. The typical alloying elements are magnesium, copper, manganese, silicon and zinc. The alloying elements are added to bring changes in properties of aluminium.

Aluminium alloys are used in engineering structures and components where light weight and corrosion resistance are required [4]. Al-alloys are used extensively in aircraft due to their strength to weight ratio.

Table 2.1 Property of pure Al, Mg and Fe

Property	Al	Mg	Fe
Density [g/cm ³]	2.7	1.74	7.87
Melting point [°C]	660	650	1535
Young modulus [GPa]	70	45	210
Brinell hardness [MPa]	95	150	140
Production per annum	2x10 ⁷	5x10 ⁵	8x10 ⁸
Relative cost	3.7	7.5	1

Figure 2.2 Life-cycle of aluminium [5]

The primary smelting industry in Iceland is also expanding. World-wide, production plants are mainly located where suitable electrical energy resources are available. In 1998, world-wide production of primary aluminium was about 22.7 million tonnes per year for and installed capacity of 24.8 million tonnes.

World-wide trends in production of aluminium are shown in Figure 2.3. Since 1950, the aluminium output factor increased by a factor 13. making aluminium the most highly consumed metal after steel. As we can see in Figure 2.3, the biggest producer in the world is China with almost 13 millions tonnes of production of aluminium.

The other main production areas are North America (6 millions tonnes), Europe (5 millions tonnes). In Europe the main producing countries are Germany, France, Spain, UK and Norway.

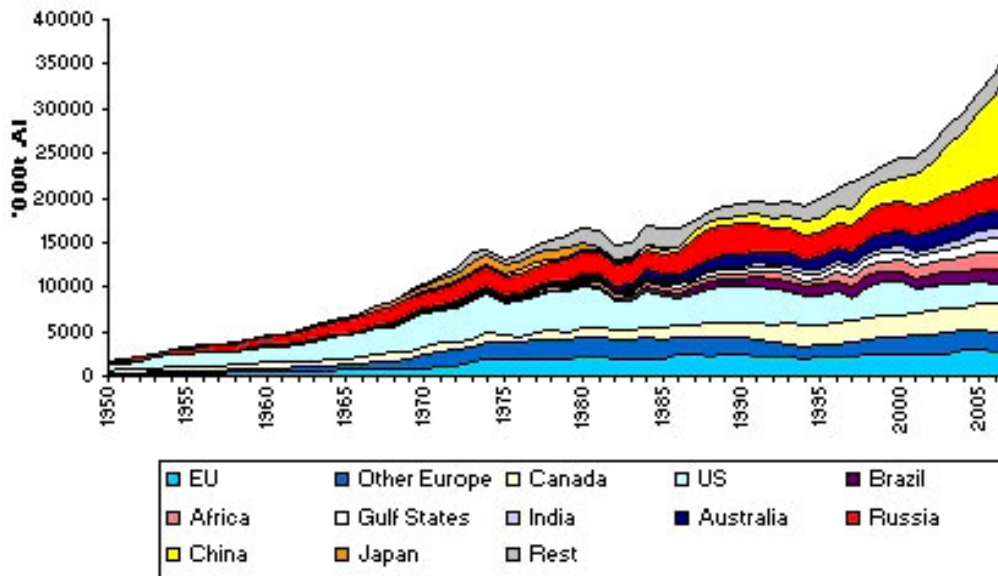

Figure 2.3 History of primary aluminium production
Main producing countries and regions from 1950-2007 [5]

2.1.2 The development of aluminium as a product

The discovery and the first commercial applications of aluminium took place at the 19th century. The enthusiasm for new materials and their possibilities was enormous.

- Transport

Aluminium usage in automotive applications has grown more than 80% in the past 5 years. A total of about 110 kg of aluminium/vehicle in 1996 is predicted to rise 250 kg by 2015 [6, 7]. Aerospace aluminium alloys with the addition of scandium it's commonly use in aerospace industry.

For the transport very important is the combination of acceptable cost, low component mass (coming from its low density), adequate mechanical properties and ease of fabrication.

Large series car production now includes aluminium as engine castings, wheels, radiators and increasingly as body parts. For general production the 5000 and 6000 series alloys provide adequate strength combined with good corrosion resistance, high toughness and ease of welding.

Aluminium and its alloys is the prime material of construction for the aircraft industry, 70% of aircraft airframe is made from Al-alloys. In aircraft the very strong 2000, 7000 and 8000 series alloys are preferred, and in military vehicles the weldable 7000 series alloys can provide ballistic properties to match steel armour [8]. Marine alloys, these alloys with their salt-water resistance are used for boat building and shipbuilding [9].

- Packaging

The 1000 series alloy is successfully used for containers and foil food wrapping to use their good corrosion resistance and barrier properties against UV light, moisture and odour. Foil is easy to form, attractively decorated and can be combined with plastic, paper or any other material. The most significant use of aluminium in packaging has been in the production of beverage cans which incorporate the "easy open ring pull" in the lid. This has rapidly grown to some 15% of all aluminium consumption and gives one hundred thousand million cans a year [8, 10].

Figure 2.4 Applications of aluminium alloys [5]

- Building and architecture

Aluminium is commonly used in buildings for a wide spectrum of applications. These include windows, doors, front for shops and prestigious buildings. Aluminium has appearance similar to other painted metals. In architecture, aluminium may also be used as decorative effects.

2.1.3 Classification of aluminium alloys

There are two principal classifications, casting alloys and wrought alloys. 85% of aluminium is used for wrought products, like rolled plate, foils and extrusions. Cast aluminium alloys yield cost effective products due to the low melting point, although they have lower tensile strengths and ductility than wrought alloys.

The alloys used for casting contain a higher amount of alloying additions than those used for wrought products. The addition of alloying elements has the effect of improving the castability of the alloys [1, 2].

Cast alloys, use a four to five digit number with a decimal point. The digit in the hundreds place indicates the main alloying elements, while the digit after the decimal point indicates the form (cast shape or ingot).

- 1xx.x series min 99% Al
- 2xx.x series copper
- 3xx.x series silicon, copper and/or magnesium
- 4xx.x series silicon
- 5xx.x series magnesium
- 7xx.x series zinc, magnesium and possibly copper
- 8xx.x series lithium

Temper designation system of age hardening alloys follows the cast designation number with a dash, letter and potentially one to three digit numbers. The definitions for the tempers are [8, 11].

F - fabricated for a certain strength level ($F_{35} = R_m \geq 350\text{MPa}$)

T- thermally treated

T1- cooled from hot working or casting and naturally aged (at RT)

T2- cooled from hot working, cold-worked and naturally aged

T3- solution heat treatment and cold worked

T4- solution heat treatment and naturally aged

T5- cooled from hot working or casting and artificially aged
(at elevated temp.)

T6- solution heat treated and artificially aged

T7- solution heat treated and stabilized

T8- solution heat treated, cold worked and artificially aged

Therefore, the standard aluminium temper designation system is also applicable to heat treatable aluminium castings. The O, T1, T4, T5, T6 and T7 tempers are used for aluminium cast alloys.

Aluminium casting alloys have been applied to various automobile parts for a long period. As a key trend, the material for engine blocks, which is one of the heavier parts, is being switched from cast iron to aluminium resulting in significant weight reduction. Aluminium engine blocks increased by the year 2000 to about 50% of all cars because of their good thermal conductivity and low thermal expansion [12, 13].

Casting alloys are used to produce dimensional complex shapes. Alloys with good castability must be able to fill the mould completely and have low sensitivity to cracking during casting [13]. Murali [14] evaluated the influence of magnesium content in the AlSi7Mg0.3 alloy with low-iron level that the absorbed energy drops significantly by about 50% with increasing magnesium content from 0.32 to 0.65%.

2.1.4 Aluminium-silicon cast alloys

Castability is improved through the addition of silicon between 4-13%. Near eutectic Al-Si-Mg alloys are one of the most common used casting alloys because of the flexibility provided by the high silicon contents and its contribution to fluidity, and their response to heat treatment which provides a variety of high-strength options.

The most common and important cast aluminium alloy system is Al-Si in the eutectic composition.

The maximum amount of Si in hypereutectic cast alloy is of 22-24%, only alloys made by power metallurgy may go to 40-50%. The low thermal expansion coefficient is exploited for pistons, the high hardness of the silicon particles for wear resistance [15].

These alloys take up fine topographical details in the mould, even in thin section. Because of addition Si we are able to form eutectic regions and to promote the formation of strengthening precipitates through the decomposition of the supersaturated solid solution in which Si and Mg are retained from casting.

The alloys with $\sim 7\%$ Si are mostly used for permanent mould castings. Those alloys solidify quickly and exhibit no long-range segregations [10, 16, 17].

Faster cooling rates, as achieved by gravity or pressure die casting, promote greater amounts of pro-eutectic α -Al than equilibrium and finer eutectic particle spacing.

The application of Al-Si alloys was studied by Flinn and Sicha [18, 19]. They presented that due to their excellent castability and good compromise between mechanical properties and lightweight, aluminium silicon alloys are the most important and widely used casting alloys in order to get components with complex shapes.

- Aluminium-silicon system

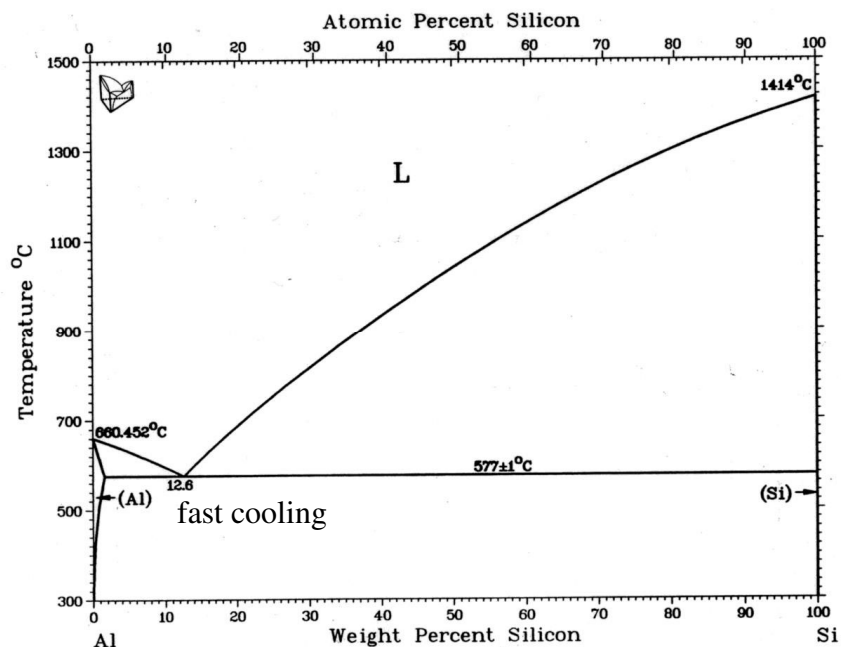

Figure 2.5 Al-Si phase diagram [16]

The Al-Si phase diagram is an example of a eutectic system, where each element has little, if any solubility in the other. Aluminium melts at 660°C while silicon melts at 1414°C. The diagram (see Figure 2.5) shows the eutectic at 12.6 wt.% Si and 577°C. The maximum solubility of Si in Al is approximately 1.65% at 577°C, and the solubility decreases with decreasing temperature. There is virtually no solubility for Al in Si at any temperature to the melting point.

Precipitation of Si does not produce any significant strengthening but causes a volume expansion doing to the diamond structure of Si [20].

2.2 Strengthening mechanisms

2.2.1 Heat treatment of aluminium alloys

Pure aluminium is too soft (has a tensile strength of about 40N/mm² and a proof strength of about 10N/mm² at RT) for most structural applications and therefore is alloyed with several elements to improve its ductility, thermal stability, corrosion resistance and increase strength. The optimum strengthening of aluminium is achieved by alloying and heat treatments. Strength at higher temperature is improved by solid-solution and second-phase hardening because at least for temperatures exceeding those of the precipitation hardening range (>230°C), [20, 21].

Al-alloys that can be heat treated to form strengthening precipitates are called heat treatable alloys. Pure aluminium is not heat treatable because not such particles can form while many heat treatable aluminium alloys are not weldable because welding would destroy the microstructure produced by careful heat treatment [22].

Magnesium after heat treatment increases substantially strength, but at the expense of ductility.

Al alloys of the Al-Si-Mg system are now being used to replace steel car body components and are subject of several studies [23, 24]. The strengthening of Al-Si-Mg alloy is based on precipitation hardening by Mg-Si precipitations. Heat treatments have three main stages: solution heat treatment, quenching and ageing.

Age hardening is the most important process to improve the mechanical properties of aluminium alloys. It requires a solid solution with a decreasing solubility of the alloying elements with falling temperatures, for instance Al-Mg₂Si, Al-Al₂Cu.

- Natural age hardening, which takes approximately from 5 to 8 days
- Artificial age hardening, which can last between 4 and 50 hours at different temperatures between 100°C and 200°C.

Alloys 2xxx, 3xxx, 6xxx and 7xxx can be strengthened by ageing.

Precipitation hardening is a treatment technique used to increase the yield strength of materials, which delay the movement of dislocations or defects.

All heat treatable Al-alloys are strengthened by precipitation hardening, which involves raising the temperature of the alloy into the single phase region so that all of the precipitates dissolve. After the fast cooling, the precipitation can form slowly at RT (natural aging) and faster at elevated temperature (100-200°C) – artificial aging [25].

Scanning and isothermal dilatometry are efficient tools to study precipitation kinetics of systems, which are connected with a change of atomic volume >10%. In the case of AlSiMg alloys, Si precipitation can be observed by dilatometry [26], but Mg₂Si not. Understanding of the precipitation kinetics of Si in Al-Si and Al-Si-Mg alloys as well as the influence of thermal treatment with different cooling rates after solution treatment were studied by Lasagni [27].

Mg-Si precipitates are the strengthening phase in Al 3xxx alloys.

2.3 Casting process

Casting is the most economical way to transfer raw materials into readily usable components, is a manufacturing simple not expensive way of forming aluminium. Cast aluminium alloys possess many benefits such as better corrosion resistance, high strength to weight ratio and excellent castability [28].

Aluminium castings are very powerful and versatile techniques for manufacturing semi- or finished products with intricate shapes. Those techniques are continuously improved and developed to satisfy the user needs and to penetrate new markets. Innovations are mainly oriented to the automobile sector which is the most important market for castings. This continual improvement and development will ensure that aluminium castings continue to play a first role in this field. Casting is most often used for making complex shapes that would be otherwise difficult or uneconomical to produce.

The size of cast elements can be from a few grams (for example a watch case) to several tones (marine diesel engine) and the shape from simple (manhole cover) to complex (6-cylinder engine block).

Al-Si-Mg alloys are one of the most common used casting alloys because of the flexibility provided by the high silicon contents and its contribution to fluidity, and their response to heat treatment which provides a variety of high-strength options. Pressure die casting, permanent mould casting is usually used for producing the aluminium and magnesium alloys components [29, 30]. Pressure die casting method is very expensive and time-consuming because of the design and recurring modification of the mould. Conventional pressure die castings cannot be heat treated due to gas trapping [31]. Permanent mould casting is usually difficult to manufacture complicated castings because of high solidification velocity of the melt.

One of the major drawbacks for conventional or even more advanced casting techniques and segregations is the formation of defects such as porosity. Of many such casting techniques available, squeeze casting has greater potential to create less defective cast components.

Generally, the squeeze casting- fabricated engineering components are fine grained with excellent surface finish and have most no porosity. They come in a variety of shapes and size. The mechanical properties of these parts are significantly improved over those of conventional castings and more sophisticated casting routes of pressure or gravity die casting.

2.3.1 Gravity die casting

In this technique, the mould is generally not destroyed after each cast but is permanent, being made of cast iron or some special steel alloy with good resistance to high temperatures. The method is often used for casting zinc and aluminium alloys.

The advantages of the gravity die casting are good mechanical properties, high dimensional accuracy and high surface smoothness. Disadvantages are high mould cost and rather slow.

A schematic view in Figure 2.6 shows the main parts constituting a classical mould for gravity die casting. Cores (inner parts of the mould) are generally made of bonded sand. Die casting mould can crack when the stress becomes bigger than the strength of the steel [32].

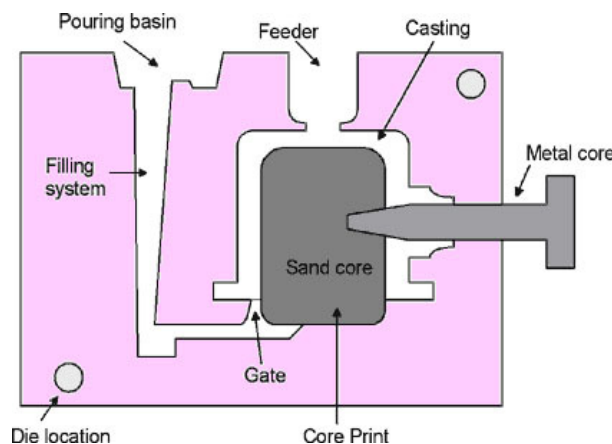

Figure 2.6 Schematic view of gravity die casting [32]

These stresses consist of residual stresses produced during tool manufacturing due to machining, grinding or heat treatment. The second type of stress is stress produced during die casting – thermo-mechanical stresses.

Residual stresses could be minimal, if mould is designed optimally and machining and heat treatment well done. The mould is repeated heated and cooled down during the process, which generates thermal stresses, which can produce thermal fatigue of the material. Thermal fatigue resistance also decreases in materials with lower thermal stability of mechanical properties and if the heat treatment is done at lower annealing temperature [33].

Figure 2.7 shows the optical microstructure of as cast AlSi7Mg0.3 alloy. The structure is fully dendritic.

Figure 2.7 Optical Microscopy of as cast of A356 samples produced by gravity die casting [34]

2.3.2 Low pressure die casting

A metal mould is positioned above a furnace containing molten metal. A riser tube extends from the bottom of the die into the molten metal. Low pressure air (15-100 kPa) is introduced into the furnace. This makes the molten metal rise up the tube and enters the mould cavity with low turbulence (see Figure 2.8). Once the casting has solidified, the pressure is released and the molten metal falls back into the bath. After cooling, the mould is opened and the casting extracted in preparation for the next cycle.

Figure 2.8 Schematic view of a low pressure die casting machine [13]

The mould filling is relatively slow to minimise turbulence and air entrapment. In order to obtain well-fed casting, the mould must be controlled to promote the directional solidification from the end of the cavity back to the riser tube [13].

The process usually produces castings with low amount of porosity. Low pressure die casting (LPDC) is mostly used for automotive parts like cylinder heads, wheels. The alloys mostly used are AlSi12, AlSi7Mg.

Advantages of low pressure die casting are that little work remains after casting; it's easy to automate, lower workshop costs than in high pressure die casting, and have better mechanical properties than in conventional sand casting.

Unfortunately, only materials with low melting points can be cast. LPDC has lower productivity than high pressure die casting and the mould is more expensive than in conventional casting.

Figure 2.9 (b) [35] shows the microstructure of as cast A356 alloy produced by low pressure die casting.

It can be seen that the white phases are α -Al primary solid phases, and the grey phases are Al-Si eutectic in the interdendritic region.

Figure 2.9 Light Optical Microscopy micrographs of low pressure die casting as-cast structure of AlSi7Mg alloy

2.3.3 Squeeze casting

Of many available casting techniques, squeeze casting has greater potential to create less defective cast components [36]. Generally, the squeeze casting fabricated engineering components are fine grained with excellent surface finish and have mostly no porosity. They come in a variety of shapes and size.

The mechanical properties of these parts are significantly improved over those of conventional castings and more sophisticated casting routes of pressure or gravity die casting. It is mainly used to fabricate high integrity engineering components with or without reinforcement [37].

Pennington [38] showed that yield strength is improved by 10-15% and elongation and fatigue strength by as much as 50-80%. Dimensional accuracy is similar to those of die casting: 0.25mm in 100mm to 0.6mm in 500mm.

The squeeze casting (SC) is a method that is a combination of casting and forging. After the melt filled the mould without turbulence it is exposed to a high pressure and starts to solidify. The pressure is during the whole solidification process what brings plastic deformation to comply with shrinkage, which improve the mechanical properties of the casting as compared to conventional casting.

As shown in Figure 2.10, the molten metal is poured into the bottom half of the preheated die (a). As the metal starts solidifying, the upper half closes the molten and applies pressure during the solidifications process (b). After solidification the upper mould section is removed and the casting is ejected by the aid of the ejector (c). The amount of pressure thus applied is not so important than in forging, and parts of great detail can be produced. The squeeze castings improved mechanical properties of the alloy and the porosity is slightly.

Figure 2.10 Direct squeeze casting principle [39]

Squeeze cast products have better mechanical properties compared to their conventionally cast counterparts due to higher density, finer grain size and more homogeneous microstructure [39, 40, 41].

A typical squeeze cast microstructure of Al-Si alloy shows Figure 2.11.

Figure 2.11 Light Optical Microscopy shows the as-cast structure of AlSi7 alloy [42]

In indirect squeeze casting (1000-1200 bar), the melt is poured into the casting chamber, which transfers it with laminar flow into the die by a hydraulic piston (see Figure 2.12). The high pressure ensures a better heat transfer, resulting in a higher rate of solidification, which leads to a finer microstructure and improved mechanical properties.

Figure 2.12 Schematic representation of the indirect squeeze casting process [37]

2.3.4 Microstructure, porosity and shrinkage in Al-cast alloys

The typical microstructure of as hypoeutectic cast-aluminium alloys consists of primary aluminium dendrites surrounded by eutectic. The structure of the eutectic depends on the solidification rate and is very important for the properties of the material. The microstructure of conventional cast samples because of the morphology growing solid-liquid is fully dendritic.

The microstructural study of Al-Si-Mg alloy with stainless steel (casting) has been investigated and focused on the both microstructures. Porosity and incomplete bonding were observed [43].

Jiang and Fan [35] studied the microstructure and mechanical properties of A356 alloy produced by low pressure die casting. The result of their study was that the microstructure of A356 alloy produced by LPDC mainly consists of α -Al phase, eutectic silicon particles and Mg_2Si phases. After T6 heat treatment, spherical eutectic silicon particles are distributed in the interdendritic region. The structure was finer and less porosity was observed compared to gravity die casting.

The natural progression of filling followed by solidification often produces internal defects, like cracks, gas entrapment, shrinkage porosity that leads to poor mechanical properties. Cracks have been found by Merlin [44] in the interdendritic eutectic region where the microstructural analysis has revealed shrinkage micro-porosity, cracked eutectic silicon with different size and morphology in the as cast condition.

Most aluminium casting alloys contract about 3-6 vol.% on solidification, which can produce porosity. This porosity can reduce the mechanical properties of the casting.

The amount of porosity in a casting depends on:

- solidification rate, and direction
- gas content,
- metal cleanliness,
- pressure in the casting
- and modification.

All those factors have been study by Fang and Granger [45]. The casting had a water-cooled chill at one end and was solidified directionally; it means the feeding was more then adequate to prevent shrinkage. The amount and size of porosity were measured by quantitative metallography using distance from the chill. Thermocouples fixed in the mould record the solidification rate at these sections. Figure 2.13 shows the amount of porosity formed in the casting.

To reduce the amount of porosity and pores, some of casting processes apply pressure to solidifying casting.

Shrinkage porosity appears in all of the casting processes. It is cavity formed due to the solidification of metal that is not fed from a supply. If there is a liquid in a mould und the gate freezes, than the casting must be smaller than the cavity shape due to solidification shrinkage. The metal can either shrink away from the wall of the mould or form a cavity within the casting. Usually in this case, section of casting that is divorce from the gate form shrinkage voids or pores. Figure 2.14 shows typical shrinkage porosity of Al-Si alloy.

Figure 2.13 Volume fraction of porosity in directionally solidified A356 alloy castings [45]

Figure 2.14 b, shows a casting defect (a pore) caused by the shrinkage of liquid during solidification of AlSi12. The microstructure consists of grey plates of silicon in a white matrix which is rich in aluminium. Although the alloy is slightly hypoeutectoid in composition, there is evidence that solidification started with primary aluminium dendrites. This is because the sample did not solidify under equilibrium conditions. Equilibrium solidification would require painfully slow cooling rates, not achievable in industrial practice.

Figure 2.14 a) Typical shrinkage porosity in a casting [46], b) pore – castings defects [47]

2.3.5 Effect of solidification rate

Rate of the solidification has an important influence on the properties of castings [13]. An alloy solidifies within a temperature interval defined by the composition of the alloy. Solid phase precipitates anywhere in the melt. Dendrites grow and form a network surrounded by melt in the shape of curved channels between the dendrites. The dendrites are small, what allows a transport of melt. When the solidification process proceeds, the dendrites become thicker and welding together defining a solid network. The channels making thinner become more difficult to supply melt to the first solidified parts, close to the mould. The shrinkage in the last part of the solidification may result pores everywhere between the dendrites in the casting. Casting that get frozen quickly can tolerate quite high contents of gas, and after slowly cooling porosity is easily formed. Oswalt and Misra [48] studied solidification rates of two different Al alloys (A356 and A357). They used dendrite arm spacing to characterize the solidification rate of the samples. To obtain different strength levels in each alloy, different aging times were employed. Increasing the aging time or adding magnesium will give us better properties of the casting. Looking to the Figure 2.15 we can see that solidification rate is indicated by the numerical values for the secondary dendrite arm spacing (SDA). SDA of the A356 alloy changing from about 25 μm which correspond to local solidification time of about 20s to about 125 μm for a freezing time of 20min.

Solidification experiments have been carried out on an Al-Si alloy as a function of temperature gradient. The samples were solidified under steady-state conditions with a constant growth rate at different and constant temperature gradients at different growth rates [49].

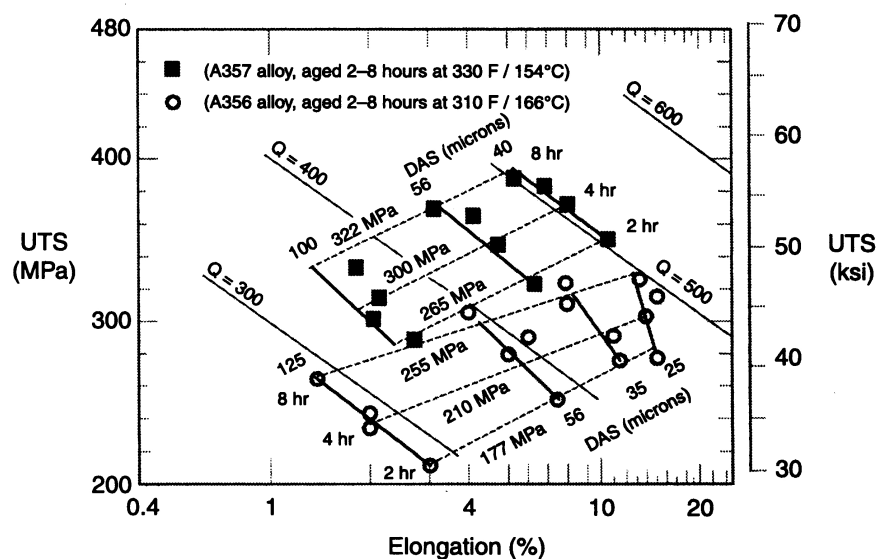

Figure 2.15 Tensile strength and quality of a356-T6 and A357-T6 alloy castings [48]

In all processes the solidification takes place through the formation of dendrites from liquid solution. The cells contains of dendritic structure corresponds to the dimensions separating the arms of primary and secondary dendrites. The dendrites are controlled by solidification rate (see Figure 2.16), [10].

Cooling rates directly control dendrite arm spacing, which influences property development and substantially improves ductility, see Table 2.17.

Figure 2.16 Dendrite arm spacing and dendrite cell size as a function of local solidification rate [10]

Table 2.17 Table of cooling rate and SDA for different casting process [10]

Casting process	Cooling rate		Dendrite arm spacing	
	°F/s	°C/s	mils	μm
Plaster, investment	1.80	1	3.94-39.4	100-1000
Green sand, shell	18.0	10	1.97-19.7	50-500
Permanent mould	180.0	100	1.18-2.76	30-70
Die	1800	1000	0.20-0.59	5-15

Solidification rate has a significant effect on the amount and distribution of porosity in a casting. This is the primary reason why the tensile properties of aluminium cast alloys depend strongly on freezing rate.

2.3.6 Inserts [50, 51, 52, 53]

Magnesium surfaces subjected to heavy bearing loads or severe wear require protection. Inserts that provide protection to the surfaces of holes can be made of various materials and attached in numerous ways.

- Cast-In Inserts

Inserts in magnesium may be fixed in place by casting the magnesium around them. Cast-in insert for use in magnesium can be made of steel, brass, bronze or other metals. Cast-in inserts become securely fixed when the cast metal shrinks around them or if the outside of the insert is grooved. Very important is to ensure that stress concentrations are not set up by sharp corners or insufficient metal around the insert.

Shrinkage of the magnesium alloy around cast-in inserts can cause high residual stress in the metal surrounding the insert. This can be reduced by preheating the insert, inserts with a wall thickness of 1.3mm (0.050 in.), see Figure 2.18, or less preheats sufficiently from contact with the hot mould and the molten magnesium. If these design and manufacturing conditions are not followed, the high residual stresses can lead to failure of the part in service brought about by stress-corrosion cracking.

Figure 2.18 Safe design dimensions for cast-in steel inserts in magnesium alloy castings. Values apply to inserts having a wall thickness greater than 1.3mm [50]

- Press-Fit and Shrink-Fit Inserts

Because of the low modulus of elasticity of magnesium, greater interference must be used for press-fit or shrink-fit inserts in magnesium than for inserts in other metals in order to obtain sufficient gripping force. An interference of 0.5 to 1 mm/m is usually satisfactory, but this range can be increased appreciable where high-torque loads are likely.

Inserts are more easily assembled by shrinking than by pressing. It is relatively easy to heat a magnesium part and thus expand a hole in the part so that it is large enough to receive an insert. If it's necessary, the insert can be cooled to facilitate insertion. Also assembly by pressing requires careful machining of both insert and hole, and proper lubrication. When large interferences are required, specifying shrink-fit inserts is best because press-fits might score the magnesium.

- Screwed-In Inserts

Various types of screwed-in inserts can be used successfully in magnesium parts. When screwed-in inserts are used, locations of threaded holes must be chosen carefully to avoid stress concentrations and to provide sufficient engagement length for the thread.

2.3.6 Objectives of this work

In this work, the interface between aluminium castings and steel inserts of four different samples has been investigated. The samples were developed by LKR for three different casting processes: gravity die casting, low pressure die casting and squeeze casting.

The following questions in this thesis:

- Which casting conditions produce interface reactions, and how much?
- Do interface reactions improve the bonding?
- How much residual stresses build up in Al at the interface during casting due to CTE mismatch?
- How develops the cast microstructure of the interface to the insert?
- Which casting defects influence the interface?
- Does the bonding strength depend on the age hardening of the Al-alloy?

Chapter 3

Description of the methodology

3.1 Materials

Different shapes of steel inserts and different Al alloys were used: rings, rods, cubes, and tubes and Al, AlSi7 and AlSi7Mg0.3 type of aluminium alloys are investigated in this work. The different AlSi-alloys were produced using gravity, low pressure and squeeze casting process by LKR, Ranshofen, Austria. Alloys are listed in Table 3.1.

Table 3.1 Different alloys and steel inserts used in this study

Sample	Casting	Alloy	Insert
Rod sample	Gravity die casting	AlSi7	St37
			18-8 Cr-Ni
Cube sample	Gravity die casting	Al (99.8%) - A 1080 AlSi7Mg0.3	St37
			18-8 Cr-Ni
Step sample	Low pressure casting	AlSi7Mg0.3	St52
Demo-axial sample	Squeeze casting	AlSi7Mg0.3	C45E

- **Rod insert**

The gravity casting consists of two suspended rod steel inserts, which are surrounded by AlSi7 casting and one of each is trimmed (Figure 3.2). The investigated samples are described by:

- Al alloy: AlSi7
- Steel insert in gravity die casting process with different melt temperature (see Table 3.3)
- Used steel St37: diameter 10mm
- Mould: 10 x 100mm long

Different surface treatments (oxidized and etched) were carried out to study the effect of interface reactions [54, 55] investigated by SEM.

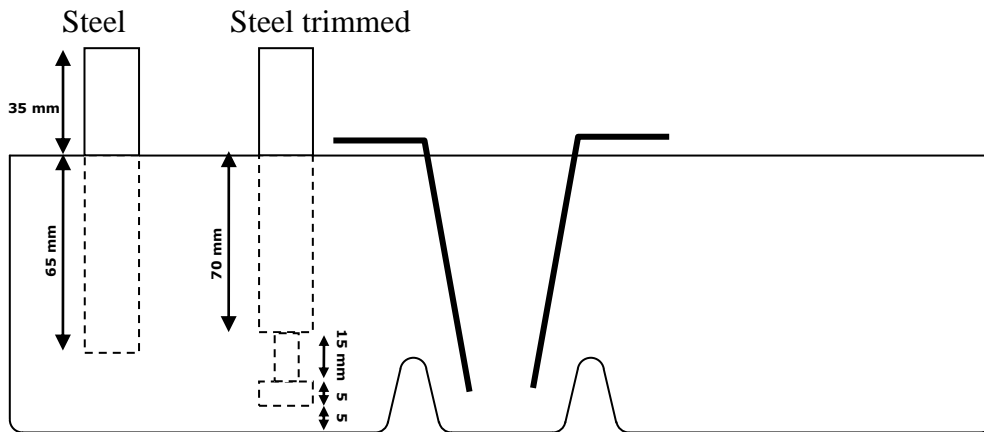

Figure 3.2 Sketch of the rod gravity cast sample

Table 3.3 Description of the investigated rod samples

Sample Nr	Insert	Alloy	T(insert) [°C]	T(melt) [°C]
2	A	AlSi7	25	700
3	B	AlSi7	25	700
5	C	AlSi7	25	750
6	D	AlSi7	25	750
7	B	AlSi7	25	750

- A** = steel St37 (no surface treatment, oxide) + trimmed
- B** = 18-8CrNi steel + surface etched, no oxide
- C** = steel (no surface treatment) + polished + etched, no oxide
- D** = C + trimmed

• **Cube insert**

Steel cubes (St37) were embedded into two different alloys: Al (99.8%) and AlSi7Mg0.3. The mould was kept at RT, 700°C or at 750°C, while the cube was immersed of RT (see Table 3.5).

Figure 3.4 Sketch of the cube sample indicated the positions of the thermocouples

Table 3.5 Description of the investigated cube samples

Sample Nr	Insert	Alloy	T(insert) [°C]	T(mould) [°C]	
1	A	Al (99.8%)	25	700	gap
2	A	Al (99.8%)	25	RT	bonding
3	A	AlSi7Mg0.3	25	700	bonding
4	A	AlSi7Mg0.3	25	RT	gap
5	B	AlSi7Mg0.3	25	750	
7	C	AlSi7Mg0.3	25	750	

- A** = steel St37 (no surface treatment)
- B** = surface etched
- C** = 18-8 Cr-Ni steel + surface etched

Two of each kind of samples, have been used for the experimental part. All the samples were cut perpendicular to the insert axis for slices 5mm thick. After cutting the sample 4 we observe, that the steel didn't stick to the aluminium along the whole interface (Figure 4.44 A, B) but cracks had been formed in the Al-casting starting from the corners of the insert. In both of the samples 1 we observed a gap along the whole insert; see Figure 4.44 C, D. Samples 2 and 3 showed microscopically good interface.

• **Step shape with rings**

Step samples (Figure 3.6) contain of St52 steel inserts without surface coating (preheated to 110°C), with outer diameter of 20mm, inner diameter of 10mm. Compound samples with AlSi7Mg alloy have been manufactured by low pressure die casting with 720°C melt temperature.

Figure 3.6 View of the low pressure die casting with different step heights (10, 15, 20, 25mm)

The samples were cut in the middle of the thickness into two equivalent halves, only samples with step height of 25mm were cut for trisect (7mm thick). Samples were separated from the array and then cut parallel to the insert axis in order to characterize the interface between aluminium casting and steel insert along its length. After the first diagonal cut in most of the samples the steel fell out of smaller half of the Al by itself. If the steel stuck to the aluminium we separated it by a second radial cut. The sample was used for the SEM and LOM in order to characterize the microstructure of the surface of the casting and the interface.

- **Demo-axial**

A demo-axial sample has been designed to demonstrate the potential of steel-aluminium composite casting [56, 57] produced by squeeze casting. It joins two inserts made from steel C45E by an AlSi7Mg cast node [56]. It was designed to withstand primarily axial (compressive or tensile) and torsional loading by force and form lock. Figure 3.7 shows an exploded drawing of the demo prototype. As the steel inserts have a complicated shape, they have been produced by CNC milling. The geometry of the steel insert is based on a tube with outer diameter of 26mm and 3mm wall thickness. The cross section of the steel insert smoothly varies along the axial direction from a circle to a triangular profile and widens again to a circle. The spacer ring has no mechanical function - it merely keeps the melt from flowing into the steel inserts. The demo prototype was quenched in water directly after the casting process.

Figure 3.7 Exploded drawing of the squeeze cast demo-axial sample with a pair of inserts of shaped steel tubes [57, 58]

Figure 3.10 Mould construction with the joining of the rods

Figure 3.11 Positions of the temperature sensors – Day 1 & 2

Figure 3.11 shows the positions of the temperature sensors, which are fixed during the experiment in order to show the cooling curves. Sensor 1 (MP1) is fixed directly in the insert, where one little hole was drilled. Sensor 2 (MP2) shows the cooling curve on the side of the mould, where sensor 4 (MP4) shows the curve at the bottom of the mould. Sensor 3 (MP3) shows cooling curve in the middle of the mould. The next two diagrams show the results of the temperature sensors fixed at different positions of the mould (Figure 3.12/3.13).

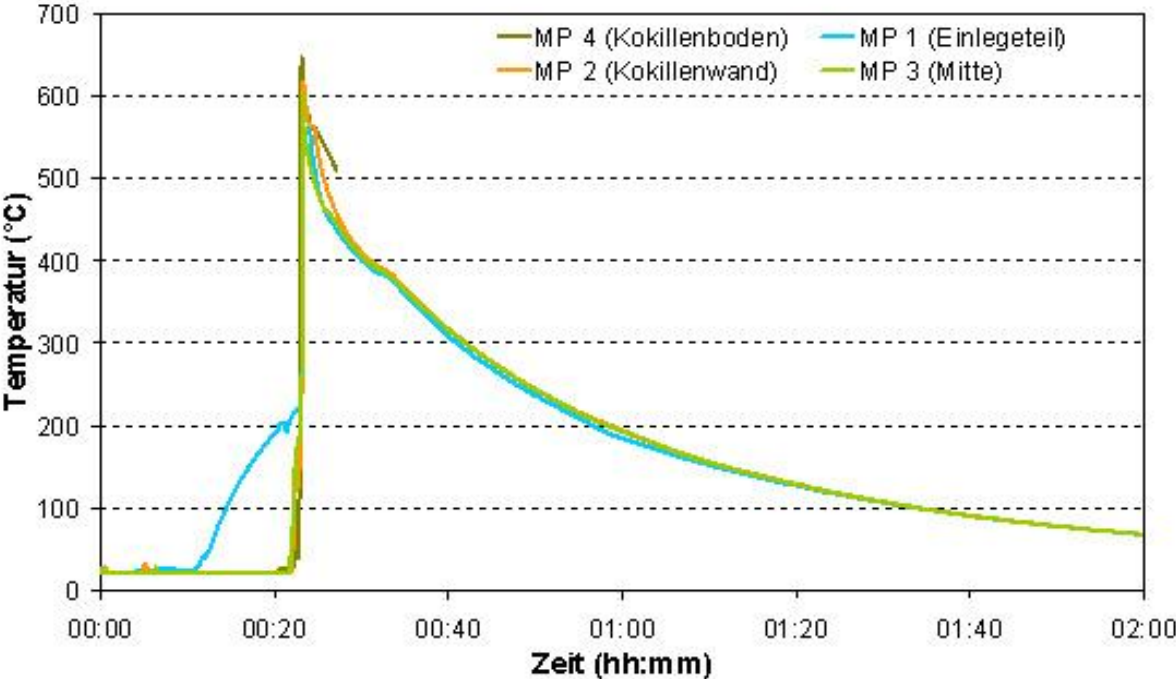

Figure 3.12 Temperature sequence (MP1 – MP4) of air cooled casting in the mould

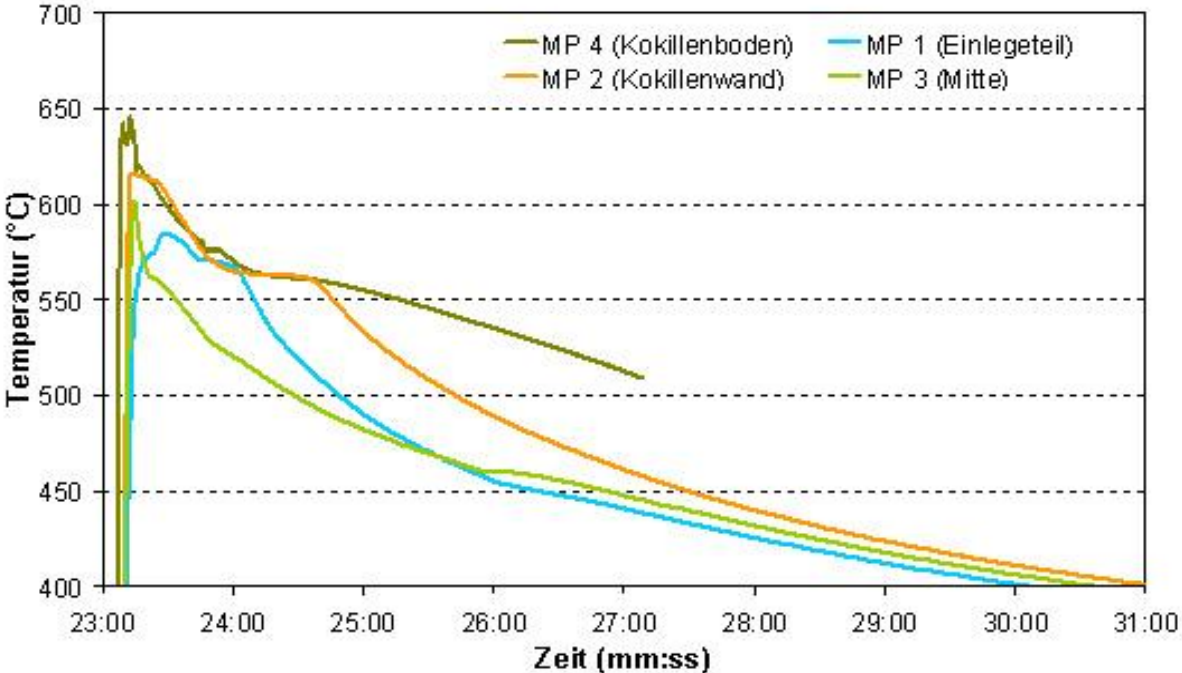

Figure 3.13 Temperature sequence (MP1 – MP4) – 400°C-700°C during solidification

Figure 3.14 Positions of the temperature sensors – Day 3

Figure 3.14 shows the positions of the sensors during the experiment without any inserts, closed at the bottom of the mould to prevent the melt do flow out. The four sensors are to show the temperature curves of the outer (MP5 & MP6) and inner (MP7 & MP8) insert. Moreover, one sensor of the sensor pair was fixed at the bottom (MP6 & MP8) of the mould and one at the top (MP5 & MP7). The next two diagrams show the results of the temperature sensors (Figure 3.15/3.16).

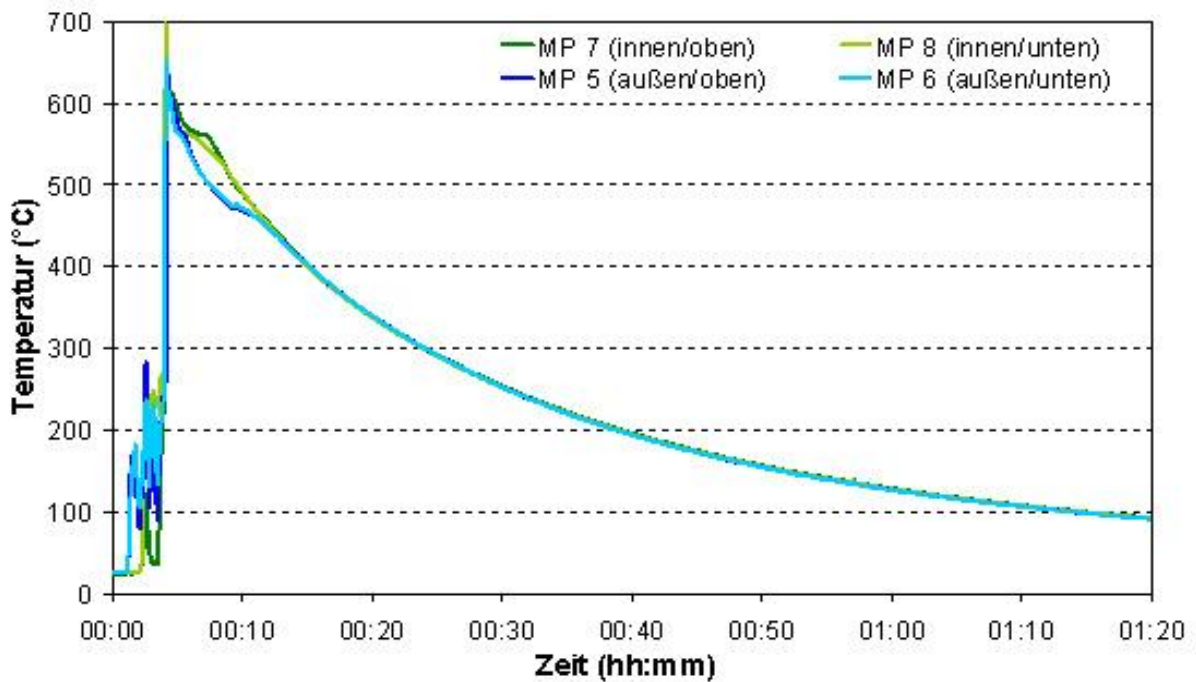

Figure 3.15 Temperature sequence (MP5 – MP8)

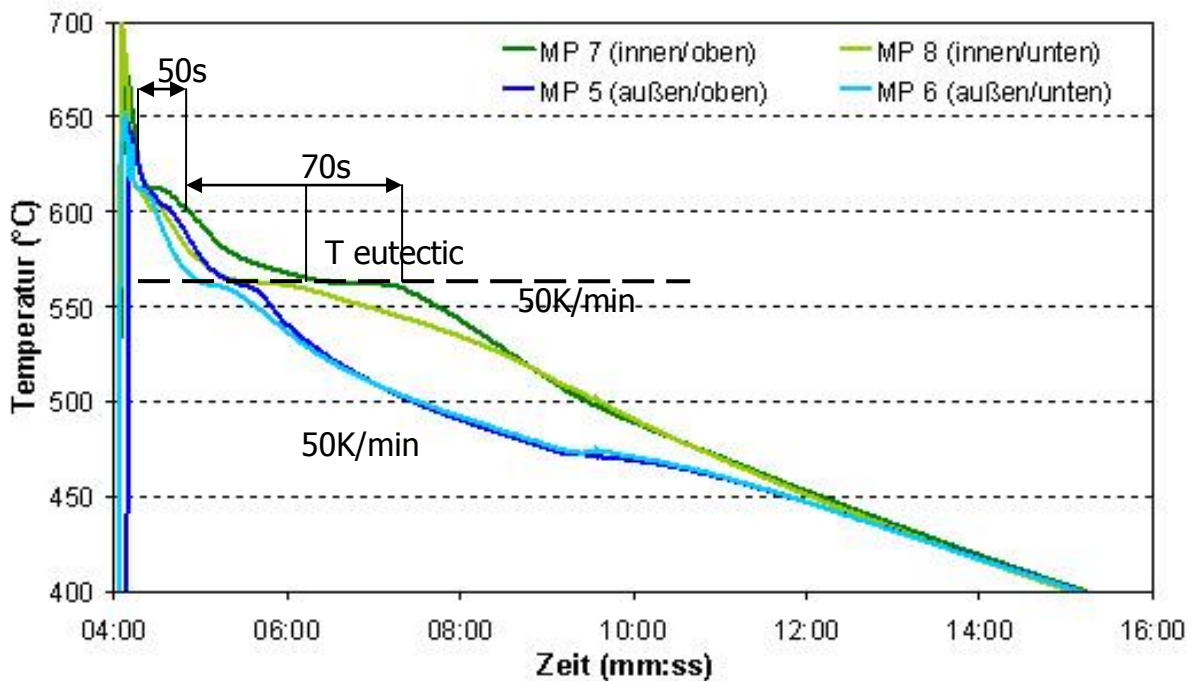

Figure 3.16 Temperature sequence (MP5 – MP8) – 400°C-700°C

3.2.2 Gravity die casting – cube sample

Cube insert of steel St37 were used with the length of 23.4mm fixed in the middle of the mould and embedded in two different alloys: Al (99.8%) and AlSi7Mg0.3 (see Figure 3.4 a). The volume ratio of Fe to Al was 1:25. The steel cube insert was etched for 45s in 10% HCL and afterwards cleaned with isopropanol and dried with hot air. During the experiment we measure the temperature at the wall of the mould, in the middle between the mould wall and the insert, and inside the insert (see Figure 3.4 b). The mould was kept at different temperatures of 700°C, 100°C and RT.

The diagrams show the cooling of the mould wall (Kanal 1) is faster then inside the insert (Kanal 3). Due to cooling from outside to inner side should be no cracks.

Sensors positions:

Kanal 1 - inside the insert

Kanal 2 - in the middle between the mould wall and insert

Kanal 3 - mould wall

Figure 3.19 Cooling diagram of pure Al (99.8%), mould at RT

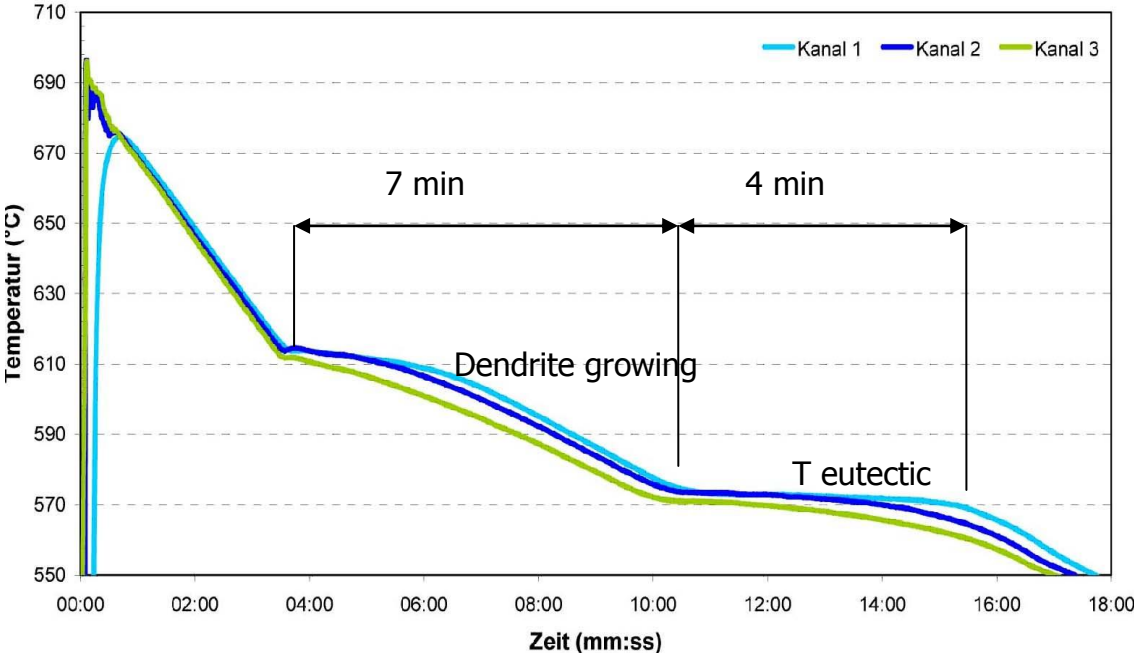

Figure 3.20 Cooling diagram of AlSi7Mg0.3, mould at 700°C

3.2.3 Low pressure die casting

Figure 3.21 Low pressure die casting: a) compound casting, b) steel insert

Step sample has been produced from AlSi7Mg0.3 alloy by low pressure die casting (see Figure 3.21). One part of the samples was removed from the mould as soon as possible and quenched in water. Another part of the samples was removed from the mould as soon as possible and cooled down in air.

Figure 3.22 a) cross section of the sample, b) characterization of the mechanical strength by pull out test

3.2.4 Squeeze casting

As already mentioned, the demo-axial sample has been manufactured using squeeze casting. Figure 3.23 a) shows the steel inserts positioned in the casting mould. Figure (b) show steel inserts (top) and a finished casting including the casting gate and four overflows (bottom). The four overflows are later broken off and the casting gate is machined off. Figure (c) shows a cross section of the sample.

After casting, the samples were removed from the mould as early as possible and immediately quenched in water. No further heat treatment was performed, so that the residual stresses that develop during the quenching process persist and determine the frictional connection of the structure [57].

Figure 3.23 Demo-axial sample as a compound casting, a) Steel insert positioned in a squeeze casting mould [58], b) Steel insert (top) and compound casting [58], c) Cross section of the sample [57]

For the cold drawn steel inserts made of C45E steel with yield strength of 660MPa. Heat flux from one material into another produces a thermal gradient at the interface as shown in Figure 3.24 a). The quotient of heat flux and thermal resistance represents the thermal contact conductance of the interface. The figure shows contact conductance at the steel-aluminium interface as a function of macroscopical gap width.

Figure 3.24 [58] a) ΔT -curve of AlSi7Mg0.3 during quenching and in the natural aged condition, b) Differential linear coefficient of thermal expansion of AlSi7Mg0.3 and C45E [59]

3.3 Thermal treatments

Different thermal treatments of the materials were carried out (Figure 3.25). The aging was carried out in a Linn High Therm furnace 70.26 at 165, 250 and 350°C followed by air cooling. Thermal treatment was performed at the step and demo-axial samples (AlSi7Mg0.3).

Sample	Heat treatments
Step sample	165°C/ 2.5h+13h 250°C/ 5h
Demo-axial sample	350°C/ 2h

Figure 3.25 Thermal treatment of AlSi7Mg0.3 with heating rate of 50K/s and air cooling

3.4 Test methods

3.4.1 Temperature measurements

To measure the cooling rate we used the whole step sample (Sample #4). The sample was heated till 510-530°C for 15min and water quenched within a few seconds. The casting was immersed into the water with the flat bottom perpendicular to the water surface. To measure the cooling rate we used special equipment with 10 thermocouples fixed on the surface and inside the sample (2mm deep), see Figure 3.26. Two thermocouples (#3 and 6) were fixed on the surface and the rest inside the sample. Sample Nr 1, 3, 7, 8 and sample 9 had been investigated. The results of the temperature measurement show Figure 4.1.

Figure 3.26 View of the low pressure die casting with different step heights (10, 15, 20, 25mm) with steel ring inserts and mounted thermocouples

3.4.2 Microstructure analysis

Samples of aluminium alloys were embedded in epoxy resin for around 24 hours. The materials were ground with 320, 500, 1000, 2400 and 4200 Strucers SiC paper for grinding with water as a coolant with rotating speed of 300RPM. After grinding the samples were polished with DP-diamond paste of 6, 3 and 1 μ m. Polishing with MgO was performed at the end, as a final polishing.

Light optical microscopy (LOM) was performed by means of a Zeiss Axioplan microscope with digital imaging system. Optical zoom between 2.5 and 100x were available in this instrument. Light optical microscopy was used to characterize the micro-structure of the casting and of the interface between aluminium and steel insert.

Scanning electron microscopy (SEM) was carried out by means of Philips XL-30 scanning electron microscope using a beam of 15kV. To observe the interface back scattered electron (BSE) mode has been used. Etching was performed in order to produce good contrast for the investigations.

The aim of the SEM analysis was to look for the interface reaction phases, porosity, cracks and the bonding between Al and steel inserts.

Figure 3.27 Instruments used for surface analysis:
a) Light Optical Microscopy, b) Scanning Electron Microscopy

3.4.3 Hardness

Samples of identical shapes used for differential scanning calorimetry and dilatometric measurements were used to perform hardness tests by means of an Universal Tester Model M1C010 provided by Emco Test.

Hardness measurements are widely used for the quality control of materials because they are quick and considered to be non-destructive tests when the marks or indentations produced by the test are in placed low stress areas.

The Brinell hardness was measured using load of 10kg and 1mm ball. The load was applied for 10 to 15 seconds. The diameter of the indentation left in the test material is measured with a low powered microscope. Before the measurements the samples were polished. The Brinell value at each state was obtained by an average of at least ten measurements.

The Brinell hardness number is calculated by dividing the load applied by the surface area of the indentation. The samples were tested in different thermal conditions.

Figure 3.28 Device for hardness measurements

3.4.4 Thermal analysis [60, 61, 62]

3.4.4.1 Thermal expansion measurements

Thermalmechanical analysis (TMA) is one of the groups of techniques termed thermal analysis (TA). Is the measurement of a change of a dimension or a mechanical property of the sample while it is subjected to a temperature regime.

For thermal-mechanical analysis we used thermal mechanical equipment TMA 2940 CE (Figure 3.29). TMA instrument monitors dimensional changes as a function of temperature. This allows determination of softening points and thermal expansion coefficients from around -70 to +1000°C.

The heart of the instrument is a moveable-core linear variable differential transformer (LVDT), the output of which is proportional to the linear displacement of the core caused by changes in sample dimensions.

The core itself is part of a quartz probe that contacts the sample. In the TMA, the sample is positioned above LVDT, on the quartz stage and the moveable probe was placed on the top of the sample (see Figure 3.29). The quartz probe with low coefficient of thermal expansion of about 0.5ppm/K transmits changes in the length of the specimen to the transducer (LVDT) with resolution of 0.1 μ m.

Temperature control of the sample is achieved by programming a low mass furnace, with heating rates between 0.01 and 200K/min that is automatically lowered to surround the sample stage and the probe, but maximum 20K/min were applied. The sample temperature is measured using a thermocouple, positioned close to the sample. An optional cooling device placed around the furnace core accommodates programmed cooling and subambient operation. The furnace is filled with nitrogen during the experiments (100ml/min). Force applied to the sample (0.001 to 1N) is generated and controlled by an electromechanical coil. The force can be held constant or varied during an experiment. The exerted pressure by the probe, with a diameter of 3mm, results in a stress of 7kPa.

Figure 3.29 TMA 2940 according to TI instruction

Dilatometric tests were carried out on TMA 2940 CE thermal mechanical analysis equipment (TA Instruments). Samples of identical shapes (5x2x15mm) were used for dilatometric measurements. The samples from the top and bottom were ground and polished to obtain parallel surfaces for the measurement.

The expansion (Δl) of the step cast sample and step sample after heating till 165 $^{\circ}$ C for 2.5h were measured between RT and 540 $^{\circ}$ C with the heating rate of 5K/min and cooling rate of 10K/min in a nitrogen atmosphere (see Figure 3.30).

The CTE curve was only calculated 10K above RT until 10K below maximum temperature to avoid smoothing errors.

Figure 3.30 Heat treatment of the step sample (AlSi7Mg0.3)

Different heat treatments were applied on AlSi7Mg0.3 alloy of the step cast sample. The sample was heated to 400°C and held for 4 hours, then cooled down with 20K/min (Figure 3.31).

Figure 3.31 Heat treatment of AlSi7Mg from the step cast sample

Isothermal expansion measurements were carried out on different alloys: Al, AlSi7Mg0.3 by means of a Bähr dilatometry. For the first measurements we used specimens from the step sample in cast condition, heated the sample to different temperatures (see Figure 3.32) with heating rate of 50K/s and cooling rate of 20K/min.

Sample of pure Al (99.8%) was heated with heating rate of 50K/s till 400°C and held for 4 hours. Afterwards with the same heating rate heated up to 540°C and held for an hour and cooled at the rate of 20K/min (see Figure 3.33).

3.4.4.2 Differential Scanning Calorimetry (DSC)

Differential Scanning Calorimetry (DSC) is a thermal analysis method that measures the heat evolution from a sample under a controlled temperature scan and is under continuous development [63].

DSC monitors heat effects associated with phase transitions and chemical reactions as a function of temperature. DSC is used to determine a wide range of thermo-physical properties of materials, including the glass-transition temperature T_g , the melting temperature T_m , and solid-solid transitions.

The DSC system used consists of the electronic system (Figure 3.38 a) and the cell, which contains its own thermocouples (temperature sensor) for monitoring differential heat flow and temperature (b). The DSC cells use a constantan disc as a primary heat-transfer element. A silver heating block, capped with a vented silver lid, encloses the constant disc.

The selected sample and reference sample are placed in pans that sit on raised portions of the disc. Heat is transferred through the constantan disc to both the samples and reference pans. Differential heat flow to the sample and reference are monitored by the chromel constantan thermocouples. The thermocouples are fixed at the junctions of the constantan disc and the chromel wafers welded to the underside of the two raised portions of the disc. Chromel and alumel wires are connected to the chromel wafers at the thermocouple junctions to measure the samples temperature. The alumel wire is for thermal balance. Purge gas, entering the heating block through an inlet the DSC cells base plate, is preheated to block temperature by circulation before entering the sample chamber through the purge gas inlet. Gas exits through the vent hole in the silver lid. Vacuum and air cooling ports in the DSC lead to openings in the cell but not directly to the sample chamber.

A bell jar, placed over the cell and sealed with an O-ring, protects the operator from evolved gases and permits cell evacuation [20].

Figure 3.38 View of the instrument DSC 2920 (from TI instruction)

DSC (Differential Scanning Calorimetry) was carried out with AlSi7Mg0.3 alloys. Two different samples were tested from the step cast sample and from the demo-axial sample in a cast condition, heated to 165°C for 10 hours and heated to 250°C for 5 hours. During measurements of the heat treated samples, a heating rate of 10K/min was used in nitrogen atmosphere. The tests in the DSC were carried out in a temperature interval between 30°C (RT) and 540°C (Figure 3.39).

Figure 3.39 Temperature-Time curves of DSC measurements of AlSi7Mg from the step cast sample

3.4.5 Compression test

Compression tests of the sample were carried out using a Gleeble Machine 1500. The temperature was controlled by a K-type thermocouple fixed in the middle of the sample (see Figure 3.40). The size of the samples used for the compression test was of $\varnothing 10 \times 15 \text{ mm}$.

Figure 3.40 View of the equipment for the compression test (Gleeble Machine 1500)

Specimens from the insert free cast sample (see Figure 3.6) have been used for this part of the experiments. Two different tests had to be done for the compression test in the laboratory at the TU Wien. The tests were performed after an annealing treatment at 350°C to eliminate precipitation hardening of the AlSi7Mg0.3 alloy by over aging.

In the first test, the samples were heated till 350°C for 3min, then were cooled down to the temperature of deformation (Figure 3.41 a), where it was held for 30sec before compression.

For the second test series we heated the samples till deformation temperature above the annealing temperature, held it 30sec before deformation (Figure 3.41 b).

The stress strain curve was evaluated to yield the flow stress at the true strain:

$$\varepsilon = 0.02$$

a)

T_d = temp. deformation
140, 170, 200, 220, 250, 300°C

Heating rate: 10 K/s

Strain rate: 0.1/s

b)

T_d = temp. deformation
400, 450, 500, 530°C

Heating rate: 10 K/s

Strain rate: 0.1/s

linear relationship

Figure 3.42 Graph showing the stress at 0.02 of the true strain with the temperature

3.4.6 X-ray diffraction analysis

The internal stresses of the aluminium around the steel insert were measured by X-ray diffraction at TU-Wien, where the $\sin^2\Psi$ method was used. The sample was cut perpendicular to the insert axis, in the middle of the thickness into two equivalent halves. The surface of the sample was polished. The lower part of the samples was used for the measurements (Figure 3.43). The stress analysis of that sample is shown in Figure 4.63.

Figure 3.44 Sketch of the sample 10 used for X-ray diffraction according to positions of measurements

Sample 10 was used in order to measure the radial stresses on the Al-steel interface, where the sample was turned in 45° steps during the measurements (Figure 3.44 b). Results from the measurement are shown in Figure 4.66.

For the Neutron Diffraction measurements we used AlSi7 alloy. The measurements were performed at Helmholtz Zentrum Berlin [64]. Results are shown in Figure 4.64.

3.4.7 Pull out test

Pull out tests were performed with as cast and heat treated demo-prototype samples. The force of the bonding between steel and Al was measured by a Zwick Z050 testing machine (Figure 3.45).

The results of the pull out tests are shown in Figure 4.67.

Figure 3.45 a) Zwick Z050 testing machine, b) tensile test

3.4.8 Laser Ultrasound

LUS is a contactless, non-destructive measurement method [65, 66], which in addition has the ability to generate and detect very high frequency ultrasound waves. It consists of a generation and a detection unit.

The generation is performed by focusing a pulsed high energy laser with pulse times in the region of picoseconds to nanoseconds on the surface of a sample [67]. These pulses, which can be mathematically approximated as Dirac pulses, lead to very high frequency and broadband ultrasound waves (from kHz to GHz).

The contactless detection can be done by different setups and geometries like standard interferometric setups (Michelson interferometer and Fabry Perot interferometer) or more sophisticated setups (e.g. photorefractive interferometers). A state of the art photorefractive interferometer with a very broad band signal response (100 kHz to 1.2 GHz) is used.

Bulk waves were generated by focussing picoseconds laser pulses with energies of 5mJ to a small spot on the inner side of the steel tube. On the opposite side (on the aluminium surface) the arriving bulk waves are detected by the photorefractive detector. The interface of the sample is scanned by revolution of the sample and subsequently stepping along the X-axis up to 22 steps 1mm each.

Laser Ultrasound measurement was performed on the demo-axial samples in a cast condition and after aging at 165°C for 2.5 hours.

Figure 3.46 Measurement setup for non destructive Laser generated ultra sound wave detection; Laser beam scanned the inner cylinder whereas the detectors scanned the outside

Figure 3.47 The demo-axial sample mounted on the step motor for LUS

Figure 3.48 Cutting of the demo-axial sample to obtain left and right tube section

Calculation of the running time:

- Longitudinal - Transversal

$$v_{long} \approx 6000 \text{ m/s}$$

$$v_{trans} \approx 3100 \text{ m/s}$$

$$s = \sqrt{(5+5)^2 + 3^2} = 10.44 \text{ mm}$$

$$t_{long} = \frac{s}{v_{long}} = 1.7 \mu\text{s}$$

$$t_{trans} = \frac{s}{v_{trans}} = 3.4 \mu\text{s}$$

- Mode converted wave

$$s_{mod} \approx \sqrt{(5+5)^2 + 3^2} = 10.44 \text{ mm}$$

$$v_{mod} \approx \frac{3000 + 6000}{2} = 4500 \text{ m/s}$$

$$t_{mod} = \frac{s_{mod}}{v_{mod}} = 2.3 \mu\text{s}$$

- Die Rayleigh Waves runs as SAW (Surface Acoustic Wave) around the surface

$$S_{rayleigh} = 3 + 10 = 13mm$$

$$V_{rayleigh} \approx 3000m/s$$

$$t_{rayleigh} = \frac{S_{rayleigh}}{V_{rayleigh}} = 4.3 \mu s$$

Chapter 4

Results

4.1 Temperature measurements on step sample

To measure the cooling rate we used the whole step sample 4g. The sample was heated till 510-530°C for 15min and water quenched within a few seconds. The casting was immersed into the water with the flat bottom parallel to the water surface.

To measure the cooling rate we used special equipment with 10 thermocouples fixed on the surface and inside the sample (2mm deep), (Figure 3.26). Two thermocouples were fixed on the surface and the rest inside the sample. The sample regions Nr 1, 3, 7, 8 and sample 9 had been investigated by metallography.

The cooling rates are evaluated from 530°C to 120°C (Figure 4.1). In the sector of the casting thickets (25mm) the cooling is the slowest (40-60K/s). The outer positions of Al cooled down by 150K/s. The thin section (10mm) reaches cooling rates between 40-160K/s. The slowest cooling we can observe in the thick section (25mm) in the steel and at the interface, where the cooling rates range between 40-70K/s.

Figure 4.1 Graph of the cooling rates from 530 to 150°C at different positions in the step sample

4.2 Metallography

4.2.1 Gravity die casting

- Rods sample

E) Sketch of the sample 2 (I) used for LOM with indicated positions of the micrographs

Figure 4.2 Light Optical Microscopy of the rod sample 2 according to positions of the micrographs indicated in Figure 4.2 E

Sample 2 (oxide) was used to characterize the micro-structure of the sample and the interface between aluminium and steel. Photomicrographs of the sample 2 close to the interface at small magnification are shown in Figure 4.2. We can observe quite normal structure, where the dendrite cell size measures from about 40µm in Figure 4.2 B to about 60µm in Figure 4.2 A. The amount of interdendritic eutectic seems to increase towards the borders of the casting.

Figure 4.3 and Figure 4.5 show the microstructure of the sample 2 and sample 5 at the section II towards the insert. The structure consists mainly of the eutectic Al-Si, with the dendrites between 50-75µm. At the position D the dendrites are bigger, growing to about 75µm, in Figure 4.6. There dendrites are similar at the interface (A, B) and few mm away inside the casting.

E) Sketch of the sample 2 (II) used for LOM with indicated positions of the micrographs

Figure 4.3 Light Optical Microscopy of the rod sample 2 according to positions of micrographs indicated in Figure 4.3 E

Figure 4.4 shows the microstructure of the Al-Si casting at the section III, along the interface (A, B, C). The finest structure we can observe at position D-G with the dendrite arms spacing $24\mu\text{m}$. The SDA increases to about $65\mu\text{m}$ along the insert, similar to the positions H. Some interdendritic porosity in between is observed.

E) Sketch of the surface of the sample (III) used LOM indicating the positions of the micrographs.

Figure 4.4 Light Optical Microscopy of the rod sample 2 according to positions of micrographs indicated in Figure 4.4 E

Figure 4.5 shows the micrographs of the sample 5 in the section I, where the steel stuck to the Al. The dendrite arm spacing changing just a little bit from about 48μm (A) to about 65μm in position E. In the sample 2 we can observe more eutectic than in sample 5.

K) Sketch of the surface of the sample 5 (I) used for LOM indicating the positions of the micrographs

Figure 4.5 Light Optical Microscopy of the rod sample 5 according to the positions of micrographs indicated in Figure 4.5 K

F) Sketch of the surface of the sample 5 (II) used for LOM indicating the positions of the micrographs

Figure 4.6 Light Optical Microscopy of the rod sample 5 according to positions of the micrographs indicated in Figure 4.6 F

E) Sketch of the surface of the sample 5 (III) used for LOM indicating the positions of the micrographs

Figure 4.7 Light Optical Microscopy of the rod sample 5 according to the positions of the micrographs indicated in Figure 4.7 E

In the section II of sample 5 towards the interface we can see in Figure 4.6 that structure consists mainly of the eutectic Al-Si, between the dendrites 50-75μm width. In the positions B, D the dendrite arm spacing measures about 55μm, whereas in the position E close to the mould the structure is much smaller (30μm).

The section III of the Al-Si casting along the interface we can observe in the Figure 4.7 A, B. The finest structure we can observe in position D with the dendrite arms spacing 5μm in the bulk of aluminium. The SDA increases to about 65μm along the insert, similar to the positions C.

In Figure 4.8 we can see the different microstructure of the Al-Si casting at the section III as indicated in Figure E. We can observe the changes of the structure, looking at the size of the SDA of about 40 μm (at the interface) to about 70 μm in a bulk of aluminium. Micrograph B shows increased eutectic zones at the interface section. B contains a significant amount of primary Si. The dendrite cells are considerably bigger (50-60 μm) in positions C, D.

E) Sketch of the surface of the sample 3 (III) used for LOM indicating the positions of the micrographs

Figure 4.8 Light Optical Microscopy of the rod sample 3 according to the positions of the micrographs indicated in Figure 4.8 E.

E) Sketch of the surface of the sample 3 (II) used for LOM indicating the positions of the micrographs

Figure 4.9 Light Optical Microscopy of the rod sample 3 according to the positions of the micrographs indicated in Figure 4.9 E

In Figure 4.9 photomicrographs at small magnification shown the same microstructure, where the dendrite cell size changes just a little, between 33μm in position A (interface) to about 44μm in position D close to the mould. The bulk of Al consists mainly of about 25% of Al-Si eutectic as we can observe.

The next figure shows the fine microstructure of the sample 7 at the section I, where the steel stuck on the Al (see Figure 4.10 A). The dendrite sells change from about 36 μm to about 44 μm . At the positions C, D we can see that the dendrites grow from the insert. Micrograph at the position E contains of interdendritic porosity.

F) Sketch of the surface of the sample 7 (I) used for LOM the indicating positions of the micrographs

Figure 4.10 Light Optical Microscopy of the rod sample 3 according to the positions of the micrographs indicated in Figure 4.10 F

D) Sketch of the surface of the sample 7 (II) used for LOM the indicating positions of the micrographs

Figure 4.11 Light Optical Microscopy of the rod sample 3 according to the positions of the micrographs indicated in Figure 4.11 D

In Figure 4.11, we can observe the different microstructure in the section A towards the insert. We can observe the changes of the structure looking at the size of the dendrite cell size. The SDA are changing from about 34μm at positions B to about 70μm about 2mm from the mould, as we can observe in Figure C. The size of the dendrites is changing a few mm from the interface. The interface consists of the Al-Si eutectic.

The next Figure 4.12 shows the microstructure of Al-Si casting in the section III. The interface A contains more of the Al-Si eutectic. The dendrite arm spacing measure about 30 μm . Big dendrites (mm) grow at some distance from the insert towards the bulk. C shows a section of a primary dendrite stem with its brands. B shows mainly primary dendrite stems in parallel orientation.

E) Sketch of the surface of the sample 7 (III) used for LOM indicating the positions of the micrographs

Figure 4.12 Light Optical Microscopy of the rod sample 3 according to the positions of the micrographs indicated in Figure 4.12 E

- **Cube samples**

In order to characterize the microstructure of the surface of the aluminium of the cube sample, the sample was ground and polished. Photomicrographs at small magnifications are shown in Figure 4.13, next to the interface. The interface consists of the Al-Si eutectic, with the dendrite arms spacing changing of about 60 μm to 300 μm (D). We can observe a dendrite structure with lots of porosity in between.

Figure 4.13 Microstructure of AlSi7Mg0.3 (cube sample)

4.2.2 Low pressure die casting

- **Step samples**

In Figure 4.14, we can see different microstructures of the Al-Si casting parallel to the step side surface of the casting process. We can observe the changes of the structure of the α -dendrites separated by the Al-Si eutectics along this plane. The size of the dendrite arm spacing is changing between 2 and 15 μm , which is caused

by solidification rate differences at different positions. Discussing the interface to the insert (Figure A, C, D, E), α -dendrites measure 2-5 μm in width. They are alternating with eutectic Al-Si₁₂ in position A, and partly in E accumulating to about 20 vol%. But in position C, D the interface consists mainly of eutectic Al-Si₁₂. Some mm away from the interface the dendrite arm spacing is about twice as big 5-10 μm (Figure B, G), and the volume fraction of the eutectic increases. The dendrite arm spacing is considerably bigger (10-15 μm) in position F, H.

According to [1] the dendrite arm spacing (SDA) <10 μm corresponds to <50 K/s solidification rates. Positions Figure 4.15 F, H may result from 20-40 K/s solidification rate.

K) Sketch of the surface of the step sample 10 used for LOM indicating the positions of the micrographs 2 mm below the surface

Figure 4.14 Light Optical Microscopy of the step sample 10 according to the positions of the micrographs indicated in Figure 4.14 K

The positions of the micrographs in Figure 4.15 along the steel inserts height are indicated in position A. The interface areas close to the step side surface of the casting consist mainly of an α -seam less than $10\mu\text{m}$ thick and about 0.1mm wide (C, E) followed by fine structured dendrites of ca. $2\mu\text{m}$ in width. The microstructure corresponds somewhat to that in Figure D, but is finer than that in Figure C resulting from $<50\text{ K/s}$ solidification rate. In the centre of the thickness of the sample (B), the dendrites increase to more than $20\mu\text{m}$ corresponding to about 5 K/s solidification rate. A few mm away from the insert similar coarse dendrites are found in Figure B; somewhat finer close to the surface in positions D, F.

G) Sketch of the surface of the step sample 7 used for LOM indicating the positions of the micrographs

Figure 4.15 Light Optical Microscopy of the step sample 7 according to the positions of the micrographs indicated in Figure 4.15 G

Photomicrograph (Figure 4.16) at small magnification shows quite normal structure, with the dendrite arm spacing of about $12\mu\text{m}$.

Figure 4.16 Light Optical Microscopy of the step sample 2

Figure 4.17 and 4.18 shows the structure of the Al-Si casting towards the interface. Discussing the interface to the insert, the α -dendrites measure $2\text{-}5\mu\text{m}$ in width. Positions B, C show increased eutectic zones at the bonded interface section. The dendrite cells are showing the finest structure, with the dendrite size much smaller ($4\mu\text{m}$) than close to surface where the cells measured about $10\mu\text{m}$. The grain size increases towards the interior of the casting. The internal structure we can observe in Figure 4.18 E, where the dendrite arms measure about $10\mu\text{m}$. Some porosity is observed.

Figure 4.17 Composed Light optical micrographs of the step sample 2 at the interface towards the steel insert 1-2 mm below the surface (depicts see Figure 4.18)

F) Sketch of the surface of the step sample 2 used for LOM indicating the positions of the micrographs

Figure 4.18 Light Optical Microscopy of the step sample 2 according to the positions of the micrographs indicated in Figure 4.18 F

In Figure 4.19 and in 4.20, we see different microstructures of the casting next to the interface. We can observe the changes of the structure looking at the size of dendrite arms. The interface consists mainly of Al-Si eutectic, as we see in position A. The dendrite arms spacing of about $3\mu\text{m}$ (A) to about $10\mu\text{m}$ (C, D) are observed.

E) Sketch of the surface of the step sample 2 used for LOM indicating the positions of the micrographs

Figure 4.19 Light Optical Microscopy of the step sample 2 according to the positions of the micrographs indicated in Figure 4.19 E

Figure 4.20 Composed micrographs of Figure 4.19 of the step sample 2

4.2.3 Squeeze casting

- **Demo-axial samples**

The structure of the bulk AlSi7Mg0.3-casting is shown in Figure 4.21 with dendrite arm spacing changing from about $24\mu\text{m}$ (b) to about $30\mu\text{m}$ in the position A with some eutectic between. The finest structure we can observe in the position C with dendrite size of about $10\mu\text{m}$.

Figure 4.22 shows the microstructure of the sample after heat treatment of $165^\circ\text{C}/2.5\text{h}$ and after pull out test (see Figure 4.67). The dendrite cells are a bit smaller than we can observe in other as cast positions.

In Figure 4.23 the microstructure of the sample with $350^\circ\text{C}/2\text{h}$ thermal condition (used for pull out test) consists of large regions ($\sim 0.5\text{mm}$) of the eutectic Al-Si, with the dendrites between $15\text{-}42\mu\text{m}$. At the position A the dendrites are bigger, growing up to $40\mu\text{m}$ with more eutectic between.

Figure 4.21 Bimodal SDA of the demo-axial sample (AlSi7Mg0.3)

Figure 4.22 Micrographs of the demo-axial sample after tensile test (heat treatment 165°C/2.5h)

Figure 4.23 Micrographs of bimodal structure of the demo-axial sample after tensile test (heat treatment 350°C/2h), bimodal SDA 10 μm/50 μm

Fig. 4.24 LOM of the demo-axial sample showing the gap in the middle of the bulk of the casting in the marked region of Figure 4.74 A

The structure of the bulk aluminium with defects of the squeeze casting process is shown in Figure 4.24. The dendrites arm spacing changes from less than $10\mu\text{m}$ to about $30\mu\text{m}$. The structure consists mainly of eutectic, with increasing eutectic zones towards the gap. Such a gap could be formed by lack of filling of the solidified dendritic structure. The sample was used for laser ultrasound measurements (see Figure 4.74 A), which shows the position of the defect.

4.2.4 Interface gaps, shrinkage pores, dendrites

In order to characterize the shrinkage of the Al along the steel insert we used rod sample. The sample was cut in the middle of the length into two halves, ground and polished perpendicular to the insert axis along the centre plane. Photomicrographs at small magnifications are shown in Figure 4.25. We can see the different microstructures of the casting next to the steel insert. We can observe the changes of the size of the dendrite arms spacing, which change from about 10 μ m (E) to about 50 μ m (G). Si segregation with primary Si we can observe in position E, F, G.

R) Sketch of the investigated sample indicating the position of the micrographs A – N

Figure 4.25 LOM of the rod sample 2 according to the positions indicated Figure 4.25 R

Micrographs 4.26 A, B showing a defect with micro-pores within the Al of the sample may be assigned to hot tearing.

Figure 4.26 SEM micrographs showing a defect with micro-pores within the Al of the cube sample 1

Figure 4.28 shows the bonding between steel and Al of the cube sample 1. The interface between the steel insert and casting part is damaged and broken. Lots of porosity is observed. Discussing the interface and surface, the pores measure between 0.1–0.9 mm in width (Figure 4.27). In some places 4.27 B the bonding looks much better than in the sample 2, but we can see lots of cracks next to the interface (Figure 4.28), with the length of the cracks changing from about 100μm to about 200μm.

Figure 4.27 SEM micrographs of the cube sample 3 (AlSi7Mg0.3 / mould 700°C) showing filling porosity

Figure 4.28 SEM micrographs of the cube sample 2 (Al/ mould RT) A) shows the structure and bonding between the steel insert and aluminium, B, C) shows cracks at the interface, parts of the edges are broken away (may stick to the insert)

4.2.5 Interface observation

The interesting part was a difference in the thickness of the sample 10 as between the Al overflow rim (< 1mm over the steel insert) and the Al bulk close to the insert. For this part of experiments we used the optical microscopy, as the micrometer screw was not enough precise. We measured the region where Al overflows the steel. We tried to know the step height and the deformation with respect to the Al bulk which shrank due to thermal expansion difference $\Delta\alpha$ where that of Al is twice as big as that of steel. ΔT is taken to be 550K.

$\Delta\alpha\Delta T = 12 \cdot 10^{-6} \cdot 550 = 0.66\%$, which gives for 15mm height 0.1mm shrinkage difference.

The average shrinkage between Al bulk and overflow rim is about 50 μm . The relative shrinkage should amount to about 0.1mm, which corresponds very well when assuming the 50 μm step on both sides. The shrinkage can be observed already less than 2mm from the border of the insert. Figure 4.31 shows a SEM micrograph of the overflow of Al over the steel insert.

Figure 4.29 Sketch of the deformation along the axis of the steel insert

The sample was cut in the middle of the thickness, perpendicular to the insert axis into two equivalent halves. The half with the overflow rim was cut along a plane parallel to insert's axis roughly through the points 2-9 (Figure 4.30). We supposed that the rest of the steel cylinder would fall out of the Al by itself, but it didn't. It sticks. Without applying any force we decided to cut the sample again more or less perpendicular through point 6. The sample fell apart. In the next part of experiments we used sample 7, which was cut in the same way as sample 10. This sample also stuck till the last cut. The bending between the insert and the surrounding casting (in both samples) was strong enough to sustain all the cutting procedures.

Figure 4.30 The distance between points in one column is about 2mm. Cutting are marked by red lines

Figure 4.31 Top view of the section of Al overflow rim over the steel insert (SEM micrographs, step sample 10). Arrow indicates the width of the deformed Al-surface

Figure 4.32 Steel insert fell apart during cutting through the points 2-9 (see Figure 4.30)

The SEM micrographs (Figure 4.33 A, B) show the cracks and reaction products in the cast part of the sample. For this part of the experiments we used sample 10 (15mm) and sample 7 (25mm). In sample 7 we did not find any cracks but we found lots of dendritic shrinkage porosity what we can see in the position D.

Figure 4.33 SEM micrographs showing the cracks in the casting at the edge positions of the insert (marked by arrows in A and B or reaction products; C) shows vertically the replica of the turning marks of the steel insert (arrow), but in the middle there are some horizontal sliding marks and (D) interdendritic porosity

Looking at the plane through the middle of the thickness, we can see gaps between the insert and the casting parts in some places (see Figure 4.34 - 4.36), but these do not open continuously. Figure 4.34 shows more or less bonded interface, which might have suffered some debonding during preparation. At the interface in positions A, B α -phase with cell sizes between 15–20 μm is observed. In the position B appears a continuous alpha layer, where there is no gap. The alpha cell sizes in position C are much smaller and drop to ca. 2 μm in position D.

Figure 4.34 Microstructure of A, B) between the casting part and steel insert, C, D) gap between Al and steel (polished surface), E) gap between Al and steel (unpolished surface)

Figure 4.35 Different contrast of LOM of the cross section of the step sample along the axis direction of insert

Photomicrographs at different magnifications of the unetched surface are shown in Figure 4.35. No chemical bonding was recognized between the steel insert and the casting alloy.

Figure 4.36 C, D shows clear gaps between aluminium and steel with some curvature in the Al casting with increased eutectic zones at the bonded interface section. The overviews in positions A-D show curved ends of the gaps. At the gaps dendrite cell diameters is of about $15\mu\text{m}$, somewhat smaller along the bonded sections, $<10\mu\text{m}$ in position D. There is no cylindrical symmetry in the microstructure.

Figure 4.36 Optical micrographs of the step sample 7 of the cross section in the middle of the thickness with local gaps

Photomicrographs (Figure 4.37) show different microstructures of the casting next to the gap. We can see the changes of the structure, looking at the size of the dendrite arms. The structure of the bulk Al-casting is shown in the position C with dendrite arm spacing of about $15\mu\text{m}$. The dendrite arms measure about $5\text{-}20\mu\text{m}$ in width and are mostly oriented in parallel, except between grains (E). Positions A, B, D-F show the borders of the Al casting towards the gap. There the direction of the solidification i.e. orientation of the dendrites can be concluded to be from the bulk to the gap. The interface to the gap consists mainly of Al-Si eutectic. So such gaps between steel insert and Al-casting were formed during solidification.

Figure 4.39 shows the intermetallic phases of the rod sample 5. The width of the islands is changing from about 20 μ m (A) to about 115 μ m in position C. The phases are mostly observed on the steel insert side. We found as well lots of porosity and cracks in the casting part of the sample.

Figure 4.39 SEM micrographs showing intermetallic islands on the cross section of the rod sample 5

Intermetallic islands of sample 7 we can observe in Figure 4.40. Different intermetallic phases are changing size from about 5µm at the position D to about 60µm (C). On this sample islands appear only on the steel side and mostly in rounded shape. Although the insert of sample 5 (Figure 4.39) had been etched, there are only a few islands of Fe-aluminides. The stainless steel insert of sample 7 shows similar interface characteristic. It seems that solidification started from the steel insert, but produced only little interface reaction, see Figure 4.40. Interface bonding was good enough to cut the samples without disintegration.

Figure 4.40 SEM micrographs showing intermetallic phases of the rod sample 7

Different kinds of intermetallic phases can be observed in Figure 4.41 (sample 2) formed by pure Al at the cube insert when solidification process from the RT mould. Interface reactions are along the whole interface. In the aluminium and steel side cracks are observed. SEM micrographs show the cracks marked by blue arrows. On the Al side the cracks are about 50µm beneath the interface. The width of the phases is from about 10µm (A) to about 13µm in (C).

Figure 4.41 Shows the intermetallic phases of the cube sample 2 (mould at RT)

SEM micrographs (Figure 4.42) showing the interface reactions of the sample 1 (Al at the 700°C). Figure C, D show clear cracks between Al and steel in the cast sample and on the steel side. The size of the intermetallic phases is changing from about 15µm at (C) to 19µm (D) in width. Small porosity is observed (C).

Figure 4.43 shows reaction islands on both sides on the cross section of the sample 3 (AlSi7 at the 700°C). The pores are considerably bigger than in sample 1 and 2. The width of the interface reaction are changing from about 80µm (E) to about 300µm at the micrograph (F).

Figure 4.42 Intermetallic phases of the cube sample 1 (Al cast, mould at the 700°C)

Figure 4.43 SEM micrographs showing intermetallic reactions of the cube sample 3 (AlSi7 cast, mould at the 700°C)

4.2.6 Shrinkage holes around cube insert

View of the 5mm thick slices of the cube sample 3 and 4 show Figure 4.44. We can observe, that the steel didn't stick to the aluminium along the whole interface (A, B), but cracks had been formed in the Al-casting starting from the corners of the insert.

Figure 4.44 View of the cube samples where the cracks in A and B (sample 4) as well as the pores in C and D (sample 1) were observed

4.3 Hardness of castings

Figure 4.45 shows the results of the Brinell hardness in the AlSi7Mg0.3 alloy after different thermal conditions. The lowest value is observed after a heat treatment of 350°C for 2h. The highest value of 106 HB shows the sample after heating to 165°C for 15h. Hardness of as cast condition increases very slightly after aging at 165°C for 2.5h.

Figure 4.45 Brinell hardness results of Demo-axial sample (AlSi7Mg0.3) after different thermal conditions

Figure 4.46 Hardness test results for different thermal conditions for the AlSi7Mg0.3 air cooled after Bähr dilatometry with heating rate of 50K/s

The hardness of AlSi7Mg0.3 as cast and after different thermal conditions using Bähr dilatometry is presented in Figure 4.46. The hardness decreases slowly after heating from 165°C to 250°C with the heating rate of 50K/s and is significantly lower after heating from as cast condition to 350°C.

Figure 4.47 depicts the Brinell value of AlSi7Mg0.3 alloy for as cast condition, after heat treatment at 165°C for 2.5h after TMA with heating rate of 5K/min and with cooling rate of 10K/min. TMA- solution treatment decreases the hardness from 87 to 56HB.

Using differential scanning calorimetry decreases the hardness value from 81HB in the 165°C/10h condition to 88HB (7% lower) after heating to 540°C with heating rate of 10K/min and with cooling rate of 20K/min (see Figure 4.48). Similar situation we can observe for the sample heated to 250°C for 5h with hardness value of 67, thereafter hardness decreases to 52HB.

Bähr dilatometry with heating rate of 50K/s and cooling rate of 20K/min changes the hardness value of the step sample (Figure 4.49).

Figure 4.47 Brinell hardness results of investigated demo-axial sample after TMA treatments at the indicated T with heating rate of 5K/min and cooling rate of 10K/min

Figure 4.48 Hardness test results of two samples from the step sample (AlSi7Mg0.3) after DSC treatments at the given temperatures with heating rate of 10K/min, cooled 20K/min

Figure 4.49 Hardness results of step sample (AlSi7Mg0.3) after Bähr dilatometry with heating rate of 50K/s, cooled with 20K/min

Figure 4.50 shows micro-hardness measurements of the as cast demo-axial sample at different location on the sample. We measured the hardness value on the sample with the dendrite arm spacing of 12 μ m, 4 μ m and on the eutectic. We can see very high differences of hardness between eutectic and arm spacing of 12 μ m. Looking on the Figure 4.51 we can observe that the hardness value of the eutectic is much higher than on the position with SDA of 50 μ m and 17 μ m.

Figure 4.50 Micro-hardness measurements of the as cast demo-axial sample at the different locations in the sample

Figure 4.59 shows several DSC runs of AlSi7Mg0.3 alloy (step and demo-axial sample) at different thermal conditions measured at 5K/min. As cast and after 165°C condition present an exothermic effect between 180-300°C (heating rate =5K/min). No exothermic effect was observed in step sample in the 250°C/5h condition. Condition of 165°C/10h shows a small exothermic effect between 200-300°C after heating at 5K/min in DSC apparatus.

Figure 4.59 DSC thermo-grams of AlSi7Mg0.3 at 5K/min in different thermal condition

4.5 Compression test

The flow curves at $1s^{-1}$ and a temperature ranging from 140°C to 350°C in as cast conditions is shown in Figure 4.60. The stress-strain curves of the AlSi7Mg0.3 (step sample) shows flow curve for the test with the $T < 350^\circ C$ (see Figure 3.41 a). Flow stress decreases with increases in deformation temperature.

Figure 4.61 shows the flow curves of the ranging temperatures from 350°C to 530°C (see Figure 3.41 b). Flow stress increases with decreasing the deformation temperature and increasing the strain rate.

Figure 4.60 Shows the flow curve for the test series Nr 1 ($T \leq 350^\circ\text{C}$)

Figure 4.61 Shows the flow curve for the test series Nr 2 ($T \geq 350^\circ\text{C}$)

4.6 Residual stresses

Figure 4.63 shows a stress analysis by X-ray diffraction of the step sample 10 of the Al in the cast alloy along a radial line from the steel interface compared with stress values in Al measured in AlSi7 without steel insert. The tangential stress increases towards the interface to 40MPa tension (stress changes from -90MPa to +30MPa by about 110MPa), [68].

Compressive stresses exist in the Al of the Al-Si casting after quenching even without any steel insert. The thermal mismatch between the Al and the Si-phase causes thermal misfit stresses as shows in Figure 4.63. Only the region close to the interface to the steel insert shows tangential tensile stresses in Figure 4.63. The residual stress in the radial direction amounts to -90 ± 30 MPa. The compressive level of in the Al Matrix seems to represent the stress originated from the quenching of the bulk and from the grinding preparation (Figure 4.64) shows the residual stresses within Al and Si after grinding AlSi7 from different temperatures: the compressive radial stresses in Al around Si inclusions dominate the tensile hoop stresses [69].

Table 4.62 Results: after quenching

	σ_r [MPa]	σ_t [MPa]
Al0	-44	34
Al5	-36	-51
Al10	-84	-54
Al15	-84	-97
Al20	-55	-86
Al25	-68	

Figure 4.63 Stress analysis by X-ray diffraction of the Al in the cast alloy quenched from 350°C along a radial line from the steel interface compared with stress values measured in AlSi7 without steel insert

Figure 4.64 Stress change in Al and Si in AlSi7 alloy without insert after quenching from different temperatures (neutron diffraction results)

Figure 4.63 shows the stress analysis of the investigated Al casting after quenching from 350°C. Compressive stresses evolve in the Al of the Al-Si casting with increasing quenching temperature even without any steel insert.

The thermal mismatch between the Al and the Si-phase causes thermal misfit stresses as shown in Table 4.65. Only the region close to the interface to the steel insert shows tangential tensile stresses in Figure 4.63, resulting from adding ca. 110MPa to the level of -90MPa compressive stress in Al.

Table 4.65 Results: after quenching from 350°C

	Aluminium	Steel
phi	σ_r [MPa]	σ_r [MPa]
0°	-62	-232
45°	-40	-236
90°	-44	-218
135°	-54	-218
180°	-79	-248
225°	-91	-287
270°	-52	-202
315°	-54	-202

Figure 4.66 gives the distribution of radial stresses in Al around 1mm outside the steel interface and 1mm inside in steel. The compressive stress in steel surpasses 200MPa whereas that in Al is below 100MPa approximately the yield strength of pure Al.

Figure 4.66 Radial stress analysis after quenching from 350°C (see Table 4.65) for the Al casting and steel close to the interface in the middle plane

4.7 Pull out test

Figure 4.67 shows results of the pull out test of the steel tubes from the as cast and heat treated demo-axial sample. The samples can resist high enough static loads, for example a tensile axial load of 26kN (S 22). Interface reaction seems to be of an effect to the bonding strength tested in tensile test. The highest value is observed in the peak aged sample 22. The bonding strength depends on heat treatment of the alloy.

Figure 4.67 Pull out test of the steel tubes from the as cast and heat treated demo-axial sample: force versus displacement curves

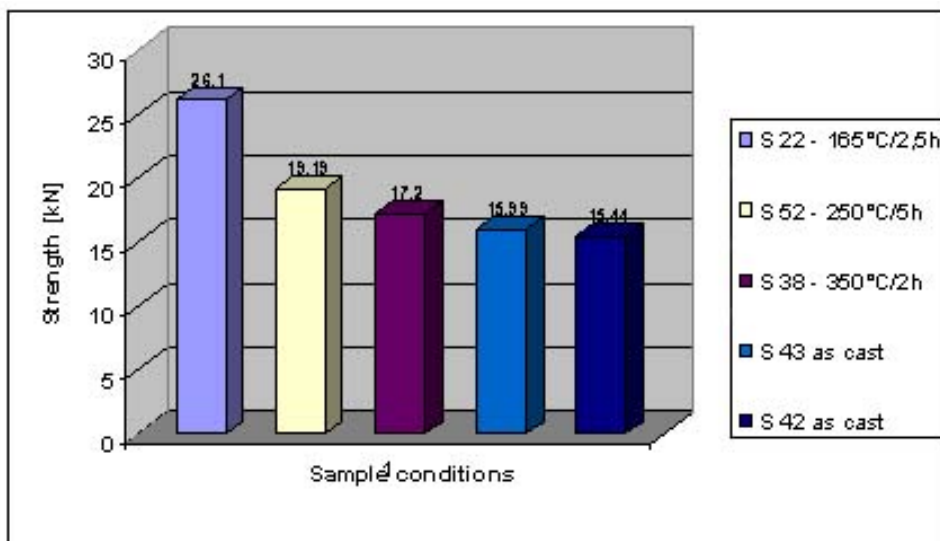

Figure 4.68 Pull out stress of the demo-axial sample carried out in the different thermal conditions

4.8 Laser Ultrasound measurements on steel-aluminium tube

Figure 4.69 shows the measurement result for an entire 360° rotation at a certain X-value. The first arriving longitudinal bulk wave can be identified at approximately 2.4µs. Between 170° and 250° rotation a defect can be identified easily by very low signal amplitude. This defect can be interpreted as debonding between steel and aluminium. Figure 4.70 A shows the maximum amplitudes between 2µs and 3µs (the green lines in Figure 4.69 B along the X-axis and φ-axis. A defect shows up with very small amplitudes in the region of 10 -15mm and at angles between 170° and 250° (Figure 4.69 B). Figure 4.70 B shows the positions of the maxima, a second defect can be seen at rotation angles between 160° and 270° [70].

Figure 4.69 [70] Shows A) Scan along the surface with the position of the minimum shown, B) Ultrasonic raw data of one 360° scan

Figure 4.70 [70] Shows A) Scan along the inner surface with the position of the maximum shown indicated by brighter colours (later arrival of the longitudinal waves), B) Scan along the surface of the sample

Figure 4.71 [70] Shows A, B) Scan along the surface with the positions of the minimum of the demo-axial sample after aging at 165°C/2.5h; C) Ultrasonic raw data of ninth step of 360° scan

Figure 4.71 shows the LUS measurements results of demo-axial sample after aging at 165°C for 2.5h, for an entire 360° rotation at a certain X-value. The first arrival longitudinal bulk wave can be identified at approximately 2.2 μ s. The defect can be interpreted as a debonding between steel and aluminium, which extends in the region 6-13mm. The position of the defect is marked on the sample in Figure 4.74 A. The microstructure around the gap we can observe in Figure 4.24.

The same sample is shown in Figure 4.72 A with the positions of minima, where the first defect shows up in the region of 1-4mm and at angles between 110-140°. The second one, we can observe at an angel between 210-250° in the region of 10-17mm. The defects are shown on the sample (see Figure 4.74 B) and used for the microstructure analysis in order to verify the defects.

Sample in as cast condition is shown in Figure 4.73. The defects are observed between 100-125° and between 240-280° in a region of 1-4mm. The defects can be interpreted as a delamination of the materials. The position of the defect is marked on the sample in Figure 4.75.

Figure 4.72 [70] Shows A, B) Scan along the surface with the positions of the minimum of the demodial sample after aging at 165°C/2.5h; C) Ultrasonic raw data of fourteenth step of 360° scan

Chapter 5

Discussion of the results

5.1 Cast microstructure

Figure 5.1 shows different bulk microstructures of the different casting processes of AlSi7 and AlSi7Mg0.3. The dendrite arm spacing of AlSi7Mg are changing from 12 μm in the fine structured regions in D to almost 100 μm in C of low pressure die casting. In case of AlSi7 alloy, the SDA are of about 34 μm (position A). Some porosity is observed as well. In the microstructure of the squeeze cast sample (D) a bimodal SDA distribution is observed.

Figure 5.1 Microstructure of the bulk of A) gravity die casting of AlSi7 rod sample, B) gravity die casting of AlSi7Mg0.3 cube sample, C) low pressure die casting of AlSi7Mg0.3 step sample and D) squeeze casting of AlSi7Mg0.3 demo-axial sample

The aluminium casting consists mainly of α -dendrites and the lamellar Al-Si12 eutectic in the interdendritic regions. Mg additions allow precipitation hardening of the α -Al [4]. The different secondary dendrite arm spacings (SDA) reflect the local cooling rate in the mould. Close to the mould, the SDA are much smaller, which means that solidification started from the cold mould.

Bimodal structures, which have been observed in demo-axial samples are shown in Figure 4.21-4.23. The structure shows dendrite distributions with separated regions of eutectic in between. In Figure 4.23 A we can observe three different areas: with α -dendrites of about $30\mu\text{m}$, with dendrites of about $50\mu\text{m}$. Both regions are separated by huge eutectic. The primary α -Al solidifies at first, then hotter melt is pressed in between mixing with the present melt resulting in a higher Si concentration, where afterwards the smaller secondary dendrite arm spacing solidifies. In Figure 4.23 E we can observe dendrites (marked by red arrows), broken by the pressure from the casting process.

The pressed in Si enriched melt solidifies last producing the larger eutectic regions.

Because the AlSi7Mg alloy belongs to the hypoeutectic alloys, those aluminium alloys begin with dendritic growth of α -Al primary solid phase and Al-Si eutectic solidified last in between the dendrite arms. In some cases, a second solidification front starts from the cold insert. If solidification started at the interface (in a hot mould) embedding fails due to heat transfer to the insert, remelting and a second solidification path from the mould causes significant porosity.

The micrographs (Figure 4.33) show that there is evidence of interdendritic shrinkage porosity at the interface of the step sample. Shrinkage strains develop not only around the steel insert, but as well in longitudinal direction causing plastification and occasionally cracking.

Gaps occur around the insert in most of the samples, caused by gas entrapment. At the bonded interface we can observe eutectic zones. The shape of the gaps in Figure 5.2 indicates that they were formed during solidification probably owing to gas entrapment unlike mechanically induced debonding.

Figure 5.2 Optical Micrographs of the middle plane of step sample with local gaps

Looking in Figure 4.25 R (rods sample) we can see the corners of the groove were not fully filled by the AlSi7 alloy due the shrinkage of aluminium. The relative shrinkage along the steel insert in the step sample should amount to about 0.1mm according to the mismatch of the coefficient of thermal expansion, which corresponds well to the measured 50 μ m steps on both sides. The shrinkage can be observed already less than 2mm from the border of the insert. Figure 4.29 shows a sketch of the overflow of Al over the steel insert.

Light optical micrographs of the step sample (Figure 4.31) show that an overflow of Al appears on both sides, where a shrinkage of the aluminium casting of about 0.1mm. The thermal mismatch for a temperature change 550K produces a relative shrinkage of Al with respect to steel 0.8% was estimated meaning that it was sliding along the cylindrical surface of the steel insert.

$$\begin{aligned} \varepsilon(\Delta T) &= \Delta CTE * \Delta T = 15 \cdot 10^{-6} * 100 = 0,15\% \text{ per } 100^\circ\text{C} \\ &+ \text{solidification shrinkage} \Rightarrow > \mathbf{0.1mm \text{ gap}} \end{aligned}$$

According to the calculation of the shrinkage step along insert of step sample, the average shrinkage between Al bulk and the overflow rim is about 50 μ m.

There is evidence of shrinkage pores, gaps around the steel inserts. Figure 4.44 A, B shows no bonding between the steel insert and the AlSi7Mg casting in cube sample. It is assumed that the melt solidified fast (without reaction) at the steel surface. The insert embedded in aluminium caused at first solidification around the insert which got heated by the melt. The solidified 'coat' was pulled away by the shrinkage of the later solidifying surrounding AlSi7Mg. This caused the formation of the cracks in the corners and of the gap between insert and casting as indicated in Figure 5.3. Such big gaps can be produced by the solidification shrinkage not compensated by melt filling. A cube of 10⁶ mm³ shrinking by 6 vol.% would produce a hole of 6·10⁴ mm³ (40mm in diameter). The hole in sample 3 (Figure 4.44 D) measures >10³ mm³ indicating that the outer shape shrank as well.

Figure 5.3 Sketch of the gravity cube cast sample showing shrinkage cracks formed on the Al side

Al-casting of cube sample (hot mould) did not embed the steel insert. A big shrinkage hole surrounded most of the steel insert (Figure 4.44 C, D). Cube sample 3 (hot mould, Figure 4.43) showed good embedding of the steel insert. The AlSi7Mg casting exhibits high micro-porosity around the insert.

Interface reaction took place at the faces of contact between steel and Al-melt, when, cracks are produced parallel to the interface, a few μm within the reaction zone of the steel. The Fe-aluminides grow columnar into the steel insert. Islands of Al-Fe-Si phases were identified on the steel insert of sample 3. Similar islands of interface reaction have been observed in the rod samples.

The steel insert of the sample cast into the cold mould was completely embedded into the Al casting (Figure 4.40). The interface reaction zone is somewhat narrower than in sample 1 indicating shorter contact time between molten Al and steel.

The Al-side of the interface was enriched in Fe (in liquid state) forming Fe-aluminides during solidification. Cracks parallel to the interface are observed within the reaction zone in the steel insert as well as in the Fe-aluminide enriched Al-casting (ca. $50\mu\text{m}$). This indicates that there was close contact between Al-melt and steel. Probably the cracks within Al formed before those in the reaction zone, because of the temperature gradient produced by the cold mould. The results of metallography chapter can be summarized in Table 5.4.

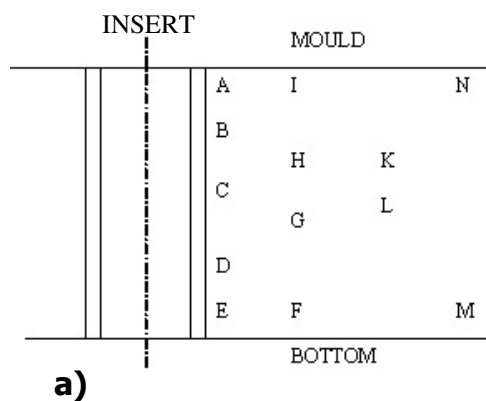

Table 5.4 Summarized information of the metallography part of the investigated samples

	Rods sample AlSi7	Cube sample (pure Al)	Cube sample (AlSi7Mg)	Step sample AlSi7Mg0.3	Demo-axial sample AlSi7Mg0.3
Casting	Gravity die casting	Gravity die casting	Gravity die casting	Low pressure die casting	Squeeze casting
Steel	St 37, 18-8 CrNi, clean steel (melt: 700°C, 750°C) and oxide (melt at 700°C)	St 37 mould: RT, 700°C	St 37 - surface etched CrNi - surface etched mould: RT, 700°C	St 52 without surface coating	C45E
SDA [μm]	SDA: 5–75 μm	SDA: 20–100 μm	SDA: 20–30 μm	SDA: 5–25 μm	SDA: 8–20 μm 50–80 μm
Solidification starts at	Solidification starts from the insert	Mould at 700°C: solidification starts from the insert; Mould at RT: solidification starts from the mould	Mould at 700°C: solidification starts from the insert; Mould at RT: solidification starts from the mould	Solidification starts from the mould	Solidification starts from the insert

Interface reactions	Intermetallic islands on cleaned steel 5-115 µm	Intermetallic phases 15-19 µm (mould 700°C)	Intermetallic islands on both sides 80-300µm	No interface reactions	No interface reactions
Gaps, cracks, porosity	- cracks - porosity	- mould at 700°C did not embed the steel insert - cracks - porosity	- porosity much bigger than in pure Al	- gaps around the insert - small porosity	-gaps in the bulk of the casting - small porosity

The experimental results of LUS showed that using ultrasound helps to identify defects of the interface between steel and aluminium. Non destructive testing by Laser Ultrasonic is very helpful to investigate the interface quality within in the bulk of material of the position of the defects which can be confirmed by LOM or SEM (Figure 4.24).

5.2 Dendrite structure in function of cooling rate

b)

	SDA µm	Measured solidification rate K/s	SDA µm [Kaufman]

Table 5.6 Measured SDA [μm]

Sample	Interface	Bulk	Mould	Gas entrapment	Shrinkage pores
Rod sample	29 - 97	5 - 75	44 - 75	no	yes
Cube sample	40 - 60	100 - 300	40 - 50	no	yes
Step sample	<3 - 20	8 - 20	12 - 20	yes	yes
Demo-axial sample	35 - 40	10 - 52	30 - 50	no	yes

5.3 Embedding strength

During solidification Al-alloys shrink by about 6 vol.%, but the yield strength is so low just below the solidification temperature that plastic deformation will occur around an insert. The linear coefficient of thermal expansion (CTE) of Fe is roughly half of that of Al ($\Delta\text{CTE} > 12\text{ppm/K}$). Assuming that thermally induced elastic stresses can build up below 300°C, the misfit volume between Fe and Al amounts to about 1 vol.%. Assuming that the iron insert is tightly embedded into the Al alloy after casting, the shrinkage difference accumulating during cooling causes elastic and plastic straining of the Al alloy surrounding the insert. The elastic stresses building up depend on the yield strength of the alloy. The elastic straining of the Al is higher than that of the steel insert owing to the modulus difference.

The shrink fit strength depends on the micro-structure of the Al-casting. The room temperature yield strength of pure Al is around 50MPa, that of the AlSi12 eutectic around 150MPa. Both increase after precipitation hardening to about 150 and >200MPa respectively. Thus a linear deformation of 0.36% causes different degrees of plastic deformation within the phases of the Al alloy equilibrating the stress around the insert: max elastic straining of Al $7 \cdot 10^{-4}$ before aging and $2 \cdot 10^{-3}$ in the eutectic, to which the Al comes close after aging.

The temperature dependence of the yield strength of AlSi7Mg0.3 approximated by the strength of 2% true strain decreases linearly from about 180MPa at 120°C to about 20MPa at 500°C. The corresponding dates for pure Al are presented for comparison in Figure 5.7.

$$\sigma_{2\%} = - 0.36 T [^{\circ}\text{C}] + 206 \text{ MPa linear relationship } (T < 550^{\circ}\text{C})$$

Figure 5.7 Graph showing the stress at 0.02 true strain changing with the temperature of AlSi7Mg and pure Al

The Al-Si system is a simple eutectic system contains two phases, fcc Al with a coordination number of 12 and diamond cubic Si with a coordination number of 4 [16], referred to the Hume-Rothery rules for substitutional solid solution the solubility of Al and Si is extremely limited [71]. The solubility of silicon in aluminium reaches a maximum 1.65 at.% at the eutectic temperature of 577°C (see Figure 2.5).

Figure 4.52 shows the comparison of changing lengths of AlSi7Mg0.3 and pure Al during heating after solution quenching from different temperatures with some calculation below according to the solubility changes.

The thermal condition changes considerably the hardness of the AlSi7Mg0.3 alloy after heating up to 350°C (see Figure 4.48). After heating the alloy by 50K/min up to 540°C, the hardness of the material decreases.

The hardness measurements showed quite similar results after different thermal treatments. Brinell hardness of as cast sample of AlSi7Mg0.3 heated up to 250°C with heating rate of 10K/s is lower than after using heating and cooling rate of 50K/s (see Figure 4.45 and 4.48).

Figure 4.48 shows the comparison of hardness values of specimens in as cast condition, before DSC experiments and after DSC cycle which means solutions treated by heating up to 540°C with heating rate of 10K/min and cooling rate of 20K/min. The lowest hardness value shows after the DSC cycles.

Micro-hardness measurements show small differences of hardness values positioned on the eutectic of the as cast and after heat treatment (350°C/2h) demo-axial sample.

The comparison of the DSC curves is shown in Figure 4.59. As shown in the figure, the two different kinds of samples have different peak temperatures. An exothermic peak of demo-axial sample starts at 240°C. That peak in the as cast step samples starts at 250°C. There is no such peak of the step sample after being heated up to 250°C.

The residual stress in the Al dendrites and the interdendritic eutectic are limited by the strain hardening of the Al-matrix in the as quenched condition, which is assumed to yield strength less than 100MPa corresponding to about 0.1% elastic strain. After aging the yield strength increases to about 150MPa increasing the elastic strain after cooling correspondingly. Cooling from 250°C aging temperatures produces less than 0.3% mismatch strain, at least ½ of which cause residual stresses. The interface stresses during cooling are unevenly distributed shear stresses parallel to the interface.

Figure 4.63 shows the stress analysis of the investigated Al casting after quenching from 350°C. Compressive stresses evolve in the Al of the Al-Si casting with increasing quenching temperature even without steel insert. The thermal mismatch between the Al and Si-phase causes thermal misfit stresses as shown in Figure 4.64. Only the region close to the interface to the steel insert shows tangential tensile stresses in Figure 4.63, resulting from adding ca 110MPa to the level of -90MPa initial compressive stresses in Al. The tangential stresses around the insert could not be measured reliably (>30MPa tensile). There is a compressive stress background (-90 MPa) within the AlSi7 alloys due the expansion mismatch between Al and Si ($\Delta CTE > 20 \text{ ppm/K}$). On top of that circumferential tensile stresses are superimposed.

Chapter 6

Conclusions

Aluminium alloys possess a number of very attractive characteristics which together with their very light weight make them extremely attractive for many applications. Aluminium alloys are up to the task, and that no matter what your needs may be there is probably a ready-made aluminium alloy to do the job [3].

- The AlSi7 castings consist of α -dendrites and eutectic Al-Si in between. The secondary dendrite arm spacing varies between 5-75 μ m reflecting locally different solidification rates. Close to the cold mold, the SAD is much smaller which means that solidification started from the mold. At the interface to the steel insert an even finer dendrite structure is observed in some cases indicating faster solidification along a thin layer around a cold steel insert. There solidification fronts from the steel insert and from the mould proceed. The interface microstructure varies from 20 to 30 vol% of AlSi12 eutectic, which indicates macro-segregations as 50% would result from an equilibrium.
- The cooling rate of the whole step casting varies from about 40K/s (next to the steel insert) to 160K/s in the Al section (near mould, 10mm thick). The difference reflects the slower solidification rate at the steel interface than in the rest of the casting (70K/s). This can be explained by heating of the steel insert by the surrounding Al-melt. Solidification starts from the upper and lower surface of the casting. It changes as well along the interface with the insert. The local solidification rates vary within 10K/s and >50K/s as deduced from the secondary dendrite arm spacing.
- Steel inserts in Al casting showed interface defects like shrinkage holes, gaps, porosity. The shrinkage holes occur along the steel insert, where the alloy solidifies last or was remelted. Frequently gas entrapment between steel and the Al melt (step sample) is formed. At the gas entrapment gaps, solidification of the Al casting progresses towards the insert (solidifies there at last). Such gaps are less frequent in the 10mm thick region.
- Interface reactions took place during contact of the oxide free steel with the Al melt, significantly more with pure Al than with the Al-Si alloys. Those interface layers of aluminides are not only formed on the steel, but as well within the adjacent aluminium. The mechanical bonding seems better if the interface reaction took place at separated spots.

- The residual stress in Al-Si alloy cause significant compressive stress of $70\pm 20\text{MPa}$ in $\alpha\text{-Al}$ after reheating and quenching due to the thermal mismatch with Si. Shrinkage of Al with respect to the steel insert is observed at least 2mm from the insert interface. Circumferential tensile stresses are superimposed close ($<2\text{mm}$) to the interface with the steel insert. The tangential stress increases towards the interface, where 40MPa tensions (stress changes from -70MPa to $+40\text{MPa}$ by about 110MPa) are measured. The residual compressive stress in the radial direction amounts to $250\pm 40\text{MPa}$.
- The yield strength of AlSiMg decreases linearly from around 180MPa at 110°C to about 20MPa at 500°C . Elastic stresses may build up during cooling only the last 200°C (yield strength ca. 130MPa at 250°C). The embedding strength seems to be provided by the surface roughness of the insert anchoring the insert. Age hardening of the AlSi7Mg alloy improves the bonding strength due the increase in yield strength (ca. 190MPa).
- Laser Ultrasound can be used for tubular inserts for non destructive testing of the interface quality, if it can be excited from the inside.

The quality of bonding of the steel insert in an Al-Si-cast alloy depends mainly on the embedding casting method. Solidification starting from the steel insert is desirable, but usually competes with the solidification front coming from the mould. Low pressure die casting produced interfaces with the least defects density. Degrading effects from interface reactions could not be verified. Naturally oxidized steel inserts do not react within usual solidification periods. High bonding strength is achieved by interfaces interlocking at the machining groves of the steel insert in absence of casting defects. The contribution of the elastic shrink fitting provides additional bonding.

*Steel inserts in Al are an established technique,
but if you look closer, you might reveal defects.*

CURRICULUM VITAE

PERSONAL INFORMATION

Name and surname: Karolina Zimnik
Address: Steingasse 6 / 8
A-1030 Wien

E-mail: kzimnik@pop.tuwien.ac.at

EDUCATION

III/2006 Vienna University of Technology, Vienna (Austria),
Institute of Materials Science and Technology and
PhD on *Interface of steel inserts in Al-Si alloy castings*

XI/2003 Vienna University of Technology, Vienna (Austria),
TU Berlin, Berlin (Germany)
Institute of Materials Science and Technology and
Project studies on *Microstructure and deformation behaviour of
coronary stents during fatigue*

VI/2003 Master thesis –
Biomechanical and clinical aspects of cervical spine implants

X/1999 – VI/2004 WROCLAW UNIVERSITY OF TECHNOLOGY, Wrocław (Poland)
FACULTY OF MECHANICS
Specialisation AUTOMATICS AND ROBOTICS

V/1998 Maturity Exam

IX/1994 – VI/1998 High School in Zgorzelec, (Poland)

ADDITIONAL COURSES

X/2002 – IV/2003 AUTOCAD 2000 POLISH LANGUAGE EDITION - BASIC COURSE
Course organised by the Wrocław University of Technology

IV/2008 Sample preparation, Vienna University of Technology,
Vienna (Austria),

WORK EXPERIENCE

XII/2003 Research and development in DESY *Deutsches Elektronen-
Synchrotron*, Hamburg (Germany) and ESRF *European Synchrotron
Radiation Facility*, Grenoble (France)

II – III/2003 Wrocław University of Technology and MAGAL Speciality
Orthopaedic Company, Wrocław (Poland)
(Upper extremity prosthesis project: architecture, mechanical design,
drafts, Medical diagnosis hardware, MRI, X-ray, tomography)

X/2002 – V/2003 Wrocław University of Technology
(Spine implants project: analyse mechanical behaviour of spine under the flexion/extension compression load)

VII – VIII/2002 *Factory of Surface Mining Machinery Joint Stock Company,*
FAMAGO S.A., Bogatynia (Poland)
(Speciality training – Automatics and Robotics)

FOREIGN LANGUAGES

- Polish (mother tongue)
- English (very good)
- German (good)

LANGUAGE TRAINING

I – II/2010 Deutsche Akademie, Vienna (Austria)

III – VI/2004 University of Vienna, *Wiener Internationale Hochschulkurse*
Vienna (Austria)

ADDITIONAL ACTIVITIES

X/2002 Member of *Interdepartmental Students Organisation of Biomechanics,*
Wrocław University of Technology, Wrocław (Poland)

V/2003 Member of *Polish Ergonomics Society*

QUALIFICATIONS

- workgroup experience
- communication
- creativity
- flexibility
- organization

INTERESTS

- medicine, medical equipment, prosthetic, implantology
- sport (ski, roller-skate)
- cinema, music, scientific & fantasy novel

OTHER

- driving licence (type A & B)
- working knowledge of MS Office (Word and Excel)
- good knowledge of 2D/3D AutoCad drawing, Ansys scripting
- basic of Matlab software
